TO THE MEMBERS OF MY DEPARTMENT,  
PAST AND PRESENT,

    this book is inscribed  
        in recognition of  
their good spirit,  
their kindly tolerance,  
their catalytic capacities

# Contributors

## **S. T. ACHAR, M.D., F.R.C.P. (C)**

Professor of Pediatrics, Madras Medical College; Director, Institute of Pediatrics, General Hospital, Madras, India.

## **JOHN A. ANDERSON, M.D., Ph.D., F.A.A.P.**

Professor and Head of the Department of Pediatrics, University of Minnesota Medical School.

## **JAMES B. AREY, M.D., Ph.D.**

Professor of Pathology, Temple University School of Medicine; Pathologist, St. Christopher's Hospital for Children.

## **HARRY E. BACON, M.D., Sc.D., LL.D., F.A.C.S., F.R.S.M.**

Professor and Head of the Department of Proctology, Temple University Medical Center; Consultant in Proctology, Douglass, Shriners, St. Mary's, St. Christopher's, Frankford, Northeastern, National Stomach, Veterans, Mercy and Paul Kimball Hospitals.

## **HENRY W. BAIRD, III, M.D., F.A.A.P.**

Assistant Professor of Pediatrics, Temple University School of Medicine; Associate Pediatrician (Neurology), Temple University Hospital and St. Christopher's Hospital for Children.

## **WILLIAM P. BARBA, II, M.D.**

Associate in Pediatrics, Temple University School of Medicine; Chief of Pediatrics, Memorial Hospital; Physician, St. Christopher's Hospital for Children and Germantown Hospital and Dispensary.

## **JOHN B. BARTRAM, M.D., F.A.A.P.**

Associate Professor of Pediatrics, Temple University School of Medicine; Director of Services for Handicapped Children, and Senior Attending Pediatrician, St. Christopher's Hospital for Children.

## **PAUL C. BEAVER, Ph.D.**

Professor of Parasitology, Department of Tropical Medicine and Public Health, Tulane University School of Medicine; Visiting Scientist, Charity Hospital; Consultant in Parasitology, U.S. Public Health Service Hospital.

## **JOSEPH B. BILDERBACK, M.D., F.A.A.P.**

Clinical Professor of Pediatrics, University of Oregon Medical School; Attending Pediatrician,

Doernbecher Memorial Hospital for Sick Children.

## **RUSSELL J. BLATTNER, M.D., F.A.C.P., F.A.A.P.**

Professor and Chairman of the Department of Pediatrics, Baylor University College of Medicine; Pediatrician-in-Chief, Jefferson Davis Hospital; Physician-in-Chief, Texas Children's Hospital; Chief of Pediatrics, Hermann Hospital.

## **WILLIAM L. BRADFORD, M.D., F.A.A.P.**

Professor and Chairman of the Department of Pediatrics, University of Rochester School of Medicine and Dentistry; Pediatrician-in-Chief, Strong Memorial and Rochester Municipal Hospitals.

## **W. EMORY BURNETT, M.D., F.A.C.S.**

Professor and Head of the Department of Surgery, Temple University School of Medicine; Chief of Surgery, Temple University Hospital; Consultant, Philadelphia General and Veterans Hospitals.

## **PHILIP L. CALCAGNO, M.D., F.A.C.P., F.A.A.P.**

Assistant Professor of Pediatrics, University of Buffalo Medical School; Attending Pediatrician, Children's Hospital; Pediatrician-in-Chief, Our Lady of Victory Hospital.

## **CHARLES C. CHAPPLE, M.D., F.A.A.P.**

Associate Clinical Professor of Pediatrics, Howard University; Chief, Research-in-Aging Division, Research and Education, Veterans Administration, Washington, D.C.

## **AMOS CHRISTIE, M.D.**

Professor of Pediatrics, Vanderbilt University School of Medicine; Pediatrician-in-Chief, Vanderbilt University Hospital.

## **DAVID B. CLARK, M.D., Ph.D.**

Associate Professor of Neurological Medicine and Pediatrics, Johns Hopkins University School of Medicine; Attending Neurologist, Johns Hopkins Hospital, Harriet Lane Home, Rosewood State Training School; Assistant Attending Neurologist, Baltimore City Hospital.

## **CHARLES DAVENPORT COOK, M.D., F.A.A.P.**

Assistant Professor of Pediatrics, Harvard Medical School; Associate Physician, Children's Hospital.

**ROBERT E. COOKE, M.D.**

Professor of Pediatrics, Johns Hopkins University School of Medicine; Pediatrician-in-Chief, Johns Hopkins Hospital; Director, Harriet Lane Home for Invalid Children.

**EDWARD C. CURNEN, M.D., F.A.A.P.**

Professor of Pediatrics, University of North Carolina School of Medicine; Chief of Pediatric Service, North Carolina Memorial Hospital.

**LOUIS K. DIAMOND, M.D., F.A.A.P.**

Associate Professor of Pediatrics, Harvard Medical School; Associate Chief of Medical Service, and Hematologist, Children's Hospital.

**ANGELO M. DI GEORGE, M.D., M.S. (Ped.), F.A.A.P.**

Assistant Professor of Pediatrics, Temple University School of Medicine; Associate Attending Pediatrician and Endocrinologist, St. Christopher's Hospital for Children; Assistant Chief of Pediatrics, Philadelphia General Hospital, Blockley Division.

**KATHARINE DODD, M.D., F.A.A.P.**

Professor of Pediatrics, University of Louisville School of Medicine; Staff, Louisville General and Children's Hospitals.

**ERNEST CARROLL FAUST, Ph.D.**

Professor of Parasitology, Tulane University School of Medicine. On leave since April, 1958—Field Coordinator, Tulane-Colombia Program in Medical Education, Facultad de Medicina, Universidad del Valle, Cali, Colombia.

**HARRY A. FELDMAN, M.D.**

Professor and Chairman of the Department of Preventive Medicine, State University of New York, Upstate Medical Center at Syracuse; Attending Physician, University and City Hospitals; Consultant, Veterans Administration Hospital.

**BENJAMIN GREELEY FERRIS, Jr., M.D.**

Associate Professor of Environmental Health, Harvard School of Public Health; Consultant in Physiology, Children's Medical Center.

**F. CLARKE FRASER, M.D., C.M., Ph.D.**

Associate Professor of Genetics and Demonstrator in Pediatrics, McGill University; Director, Department of Medical Genetics, The Montreal Children's Hospital.

**JACOB BERNARD FRIEDMANN, M.D.**

Associate Professor of Anesthesia, Temple University School of Medicine; Attending Anesthesiologist, St. Christopher's Hospital for Children.

**LYTT I. GARDNER, M.D., F.A.A.P.**

Professor of Pediatrics, State University of New York, Upstate Medical Center at Syracuse; At-

tending Pediatrician, Syracuse Memorial Hospital.

**SYDNEY S. GELLIS, M.D.**

Professor and Chairman of the Department of Pediatrics, Boston University School of Medicine; Lecturer on Pediatrics, Harvard Medical School; Director of Pediatrics, Boston City Hospital; Consultant, Children's Medical Center.

**ELI GOLD, M.D.**

Assistant Professor of Pediatrics, Western Reserve University School of Medicine; Visiting Pediatrician, Cuyahoga County Hospital; Assistant Pediatrician, University Hospitals.

**GEORGE M. GUEST, M.D., F.A.A.P.**

Professor of Research Pediatrics, University of Cincinnati College of Medicine; Attending Pediatrician, Cincinnati Children's and General Hospitals.

**ARILD E. HANSEN, M.D., Ph.D., F.A.A.P.**

Professor and Chairman of the Department of Pediatrics, University of Texas, Medical Branch.

**JEROME S. HARRIS, M.D., F.A.A.P.**

Professor and Chairman of the Department of Pediatrics, and Associate Professor of Biochemistry, Duke University School of Medicine; Pediatrician, Duke Hospital.

**ROBERT H. HIGH, M.D., M.S. (Ped.), F.A.A.P.**

Associate Professor of Pediatrics, Temple University School of Medicine; Director, In-Patient Services, St. Christopher's Hospital for Children; Consultant in Pediatrics, U.S. Naval Hospital.

**PAUL H. HOLINGER, M.D., F.A.C.S., F.A.C.P.**

Professor of Bronchoesophagology, Department of Otolaryngology, University of Illinois College of Medicine; Senior Attending Bronchoesophagologist, St. Luke's Hospital; Attending Bronchoesophagologist, Children's Memorial and Research and Educational Hospitals.

**CHEVALIER L. JACKSON, M.D., F.A.C.S.**

Professor of Laryngology and Bronchoesophagology, Temple University School of Medicine.

**CHARLES A. JANEWAY, M.D., F.A.A.P.**

Thomas Morgan Rotch Professor of Pediatrics, Harvard Medical School; Physician-in-Chief, Children's Hospital.

**JOSEPH A. JOHNSTON, M.D., F.A.C.P., F.A.A.P.**

Pediatrician-in-Chief, Henry Ford Hospital, Detroit.

**SAMUEL KAPLAN, M.D.**

Assistant Professor of Pediatrics and Internal Medicine, University of Cincinnati College of Medicine; Cardiologist, Children's and General

Hospitals; Consultant, U.S. Air Force, Wright Patterson Air Force Base, and Cardio-respiratory Unit, Jewish Hospital.

**NORMAN KENDALL, M.D., M.S. (Ped.), F.A.A.P.**  
Assistant Professor of Pediatrics, Temple University School of Medicine; Attending Pediatrician, St. Christopher's Hospital for Children.

**E. GILLET KETCHUM, M.A.**  
Director, The Reeducation Clinic, The Institute of the Pennsylvania Hospital.

**ANN G. KUTTNER, M.D., Ph.D.**  
Associate Professor of Pediatrics, New York University-Bellevue Medical Center; Member of the Medical Board, Irvington House.

**DEAN M. LIERLE, M.D., M.S., Sc.D.**  
Professor and Chairman of the Department of Otolaryngology and Maxillofacial Surgery, State University of Iowa Medical School.

**SHERMAN LITTLE, M.D., F.A.A.P.**  
Professor of Pediatrics and of Psychiatry, University of Southern California School of Medicine; Director of Psychiatric Service, Children's Hospital Society.

**ROBERT A. LYON, M.D., F.A.A.P.**  
Professor of Pediatrics, University of Cincinnati College of Medicine; Assistant Medical Director, Children's Hospital; Attending Physician, Cincinnati General Hospital.

**JOHN S. McGAVIC, M.D., M.S. (Surgery)**  
Professor of Ophthalmology, Temple University School of Medicine; Professor of Clinical Ophthalmology, University of Pennsylvania Graduate School of Medicine; Attending Ophthalmologist, Temple University Medical Center and Bryn Mawr Hospital; Civilian Consultant, Valley Forge Army Hospital.

**ROBERT JAMES McKAY, JR., M.D., F.A.A.P.**  
Professor and Chairman of the Department of Pediatrics, University of Vermont College of Medicine; Chief of Pediatric Service, Mary Fletcher Hospital; Attending Pediatrician, De Goesbriand Memorial Hospital.

**IRVINE McQUARRIE, M.D., Ph.D., F.A.A.P.**  
Director of Research, The Bruce Lyon Memorial Research Laboratory of the Children's Hospital of the East Bay. Formerly Professor and Head of the Department of Pediatrics, University of Minnesota Medical School.

**MAURY MASSLER, D.D.S., M.S.**  
Professor and Head of the Department of Pedodontics, University of Illinois College of Dentistry; Dental Consultant, Research and Educational Hospitals.

**ROBERT W. MILLER, M.D., M.P.H.**  
Chief of Pediatrics, Atomic Bomb Casualty Commission, Hiroshima, Japan.

**JOHN ROYAL MOORE, M.D.**  
Professor of Orthopedic Surgery, Temple University School of Medicine.

**DAVID MYERS, M.D., F.A.C.S., F.I.C.S.**  
Professor and Head of the Department of Otorhinology, Temple University Medical Center; Attending Otorhinologist, St. Christopher's Hospital for Children.

**WALDO E. NELSON, M.D., Sc.D., F.A.A.P.**  
Professor and Head of the Department of Pediatrics, Temple University School of Medicine and Hospital; Medical Director, St. Christopher's Hospital for Children.

**ROBERT H. PARROTT, M.D., F.A.A.P.**  
Clinical Professor of Pediatrics, Georgetown and George Washington University Schools of Medicine; Physician-in-Chief and Director of Research Foundation, Children's Hospital.

**DANE G. PRUGH, M.D., F.A.A.P.**  
Associate Professor of Psychiatry and Pediatrics, University of Rochester School of Medicine and Dentistry; Senior Associate Psychiatrist and Pediatrician, and Head, Child Psychiatry Division, Department of Psychiatry, Strong Memorial Hospital.

**MILTON RAPOPORT, M.D.**  
Professor of Pediatrics, University of Pennsylvania School of Medicine and Graduate School of Medicine; Senior Pediatrician, Children's Hospital of Philadelphia.

**JULIUS B. RICHMOND, M.D., F.A.A.P.**  
Professor and Chairman of the Department of Pediatrics, State University of New York, Upstate Medical Center at Syracuse; Attending Pediatrician, Syracuse Memorial Hospital.

**FREDERICK C. ROBBINS, M.D., F.A.A.P.**  
Professor of Pediatrics, Western Reserve University School of Medicine; Director, Department of Pediatrics and Contagious Diseases, Cuyahoga County Hospital; Associate Pediatrician, University Hospitals.

**HOWARD W. ROBINSON, Ph.D.**  
Professor of Physiological Chemistry, Temple University School of Medicine.

**ALBERT H. ROWE, M.D., M.S., F.A.C.P.**  
Lecturer (Emeritus) in Medicine, University of California Medical School; Allergist, Samuel Merritt Hospital; Consulting Allergist, Oakland Naval Hospital.

**MITCHELL I. RUBIN, M.D., F.A.A.P.**

Professor and Head of the Department of Pediatrics, University of Buffalo School of Medicine; Pediatrician-in-Chief, Children's Hospital.

**ISAAC SCHOUR, D.D.S., Ph.D.**

Professor and Head of the Department of Histology, and Dean, University of Illinois College of Dentistry.

**T. F. McNAIR SCOTT, M.D., F.R.C.P.**

Research Professor of Pediatrics, University of Pennsylvania School of Medicine; Senior Physician and Director of Research, Children's Hospital of Philadelphia.

**MILTON J. E. SENN, M.D., F.A.A.P.**

Sterling Professor of Pediatrics and Psychiatry, and Chairman of the Department of Pediatrics, Yale University School of Medicine; Pediatrician-in-Chief, Grace-New Haven Community Hospital.

**THOMAS E. SHAFFER, M.D., F.A.A.P.**

Professor of Pediatrics and of Preventive Medicine, Ohio State University College of Medicine; Attending Pediatrician, Children's and University Hospitals.

**ROBERT E. SHANK, M.D.**

Danforth Professor of Preventive Medicine, Washington University School of Medicine; Associate Physician, Barnes Hospital.

**HARRY C. SHIRKEY, M.D., F.A.A.P.**

Assistant Clinical Professor of Pediatrics and Associate Professor of Pharmacology, University of Cincinnati College of Medicine; Assistant Director (Pediatric Division), Cincinnati General Hospital; Attending Staff, Cincinnati, Children's, General, Christ and Good Samaritan Hospitals.

**CHARLES E. SMITH, M.D., D.P.H.**

Dean, School of Public Health, University of California; Member, California State Board of Health.

**CLEMENT A. SMITH, M.D., Sc.D. (Hon.), F.A.A.P.**

Associate Professor of Pediatrics, Harvard Medical School; Physician, Children's and Infants Hospitals; Director of Research on the Newborn, Boston Lying-in Hospital.

**NATHAN J. SMITH, M.D.**

Alfred Dorance Daniels Professor of Diseases of Children and Chairman of the Department of Pediatrics, University of Wisconsin School of Medicine.

**EARLE H. SPAULDING, Ph.D.**

Professor and Head of the Department of Microbiology, Temple University School of Medicine; Bacteriologist, Temple University Hospital.

**ALEX J. STEIGMAN, M.D., Sc.D. (Hon.), F.A.A.P.**

Professor and Head of the Department of Pediatrics, University of Louisville Medical School; Pediatrician, Children's and Louisville General Hospitals.

**STUART SHELTON STEVENSON, M.D., M.P.H., F.A.A.P.**

Professor and Chairman of the Department of Pediatrics, Seton Hall College of Medicine and Dentistry. Formerly Research Professor of Pediatrics, University of Pittsburgh School of Medicine; Senior Pediatrician, Children's Hospital.

**JOSEPH STOKES, JR., M.D., Sc.D. (Hon.), F.A.A.P.**

William H. Bennet Professor of Pediatrics and Chairman of the Department of Pediatrics, University of Pennsylvania School of Medicine; Physician-in-Chief, Children's Hospital of Philadelphia.

**HAROLD S. STUART, M.D., F.A.A.P.**

Professor (Emeritus) of Maternal and Child Health, Harvard School of Public Health; Consultant to Child Health Division, Children's Medical Center.

**VICTOR C. VAUGHAN, III, M.D., F.A.A.P.**

Professor and Chairman of the Department of Pediatrics, Medical College of Georgia; Chief Pediatrician, Eugene Talmadge Memorial Hospital; Pediatric Consultant, University Hospital.

**ARTHUR JUDSON WALKER, M.D., C.M., D.T.M.**

Associate Professor of Tropical Medicine, Tulane University School of Medicine. On leave as Medical Parasitologist to Malaria Eradication, Pan American Sanitary Bureau, World Health Organization.

**JOSEF WARKANY, M.D.**

Professor of Research Pediatrics, University of Cincinnati School of Medicine; Attending Pediatrician, Children's and Cincinnati General Hospitals.

**RALPH J. P. WEDGWOOD, M.D.**

Assistant Professor of Pediatrics and Preventive Medicine, Western Reserve University School of Medicine; Associate Pediatrician, University Hospitals; Visiting Pediatrician, Cuyahoga County Hospital; Pediatrician-in-Charge, Rainbow Hospital for Crippled Children.

**ARMINE T. WILSON, M.D.**

Chief of Bacteriology, Alfred I. du Pont Institute, Wilmington, Delaware.

**CARROLL S. WRIGHT, M.D.**

Professor of Dermatology, Temple University School of Medicine; Professor of Clinical Dermatology, University of Pennsylvania Graduate School of Medicine; Dermatologist, Temple University, Abington, Shriners, Skin and

Cancer Hospitals and St. Christopher's Hospital for Children.

**HERMAN YANNET, M.D., F.A.A.P.**

Associate Clinical Professor of Pediatrics, Yale University School of Medicine; Attending Pediatrician, New Haven Hospital; Director, Southbury Training School; Consultant in Pediatrics, Waterbury Hospital.

# Preface to the Seventh Edition

THE PREPARATION of a textbook which proposes something approximating complete coverage of a major division of medicine is a humbling endeavor. As with the previous editions, it must suffice to say that contributors and editor have again done their best to serve the student and practitioner in their search for a better understanding of the medical problems of infants and children.

This edition, without shifting from the pattern of a text to that of a compendium, is somewhat shorter than its immediate predecessor. The accomplishment of this goal has not been without "blood, sweat and tears." The tolerance of the individual contributors in permitting some reconstruction of their literary effort can be appreciated only by those who have known the joys of literary conception. The toil of tightening and "containing" will be known only to those who have made the effort to avoid the need for the closing remark, "I regret my letter is so long, I had not the time to be brief."

Again, the major portion of credit is to the contributors, and the majority of criticism must be borne by the editor.

It is not possible to enumerate the extent of change in the various divisions. In certain ones, including Clinical Appraisal of Infants and Children, Parenteral Fluid Therapy, Drug Therapy, Anesthesia, Prenatal Factors in Diseases of Children, The Newborn Infant, Tuberculosis, Rickettsial Diseases, Mycotic Infections, The Respiratory Tract, The Nervous System, Convulsive Disorders, Cerebral Palsy and Orthopedic Pediatrics, there are completely new chapters by new contributors or new hands working with the authors of the preceding edition. In addition, there are several new sections, including Tropical Eosinophilia, Kala-azar, Cirrhosis of the Liver in Indian Children, Pulmonary Ventilation in Health and Disease, Mesenchymal Diseases, Behavior Problems Associated with Organic Brain Damage, and The Physician and the Child with a Handicap. Throughout the book there has been a "word-by-word" revision or reappraisal. We can only hope that the result will justify the labor.

No attempt has been made to provide a comprehensive bibliography. We have, however, attempted to include references to articles containing extensive bibliographies for as many subjects as possible.

Many persons other than the contributors have participated in this revision, and, although we cannot mention them all, we recognize our indebtedness to them. These include the many who have given constructive criticisms, who have lent encouragement and have confessed to usage of this book. Our colleagues at St. Christopher's Hospital for Children and in other departments of Temple Uni-

versity School of Medicine have without intention placed us deeply in their debt. Specifically we acknowledge the help and guidance of Drs. Carroll F. Burgoon, Samuel L. Cresson, George E. Farrar, Daniel S. Fleisher, Joseph M. Garfunkel, Nancy Huang, John A. Kirkpatrick, John W. Lachman, Arthur E. McElfresh, Richard W. Olmsted, George P. Pilling, IV, Helen Reardon, Howard H. Steel and Robert E. Wells. Of those outside our medical school group, we must mention the help of Drs. Carroll F. Palmer and Phyllis Q. Edwards in the section on Tuberculosis. Dr. Richmond, likewise, acknowledges the assistance of Dr. Edward Lis.

Editorially, this book continues in the truest sense to be a family project. No person has participated to the extent Mrs. Nelson has. Her hand is evident on every page. Without her keen perceptiveness and deep devotion to detail this book would not exist in its present form. In the strictest sense she is co-editor.

Jane (Mrs. Edward F. Beatty, Jr.), now our "literary secretary," is constantly searching for increasing accuracy and adequacy of expression. Ann (Mrs. Richard E. Behrman) has found time in the midst of her own pediatric activities to continue to participate, and Bill, although "Uncle Sam" has temporary control of him, has not reneged when on leave.

To the members of the Saunders Company who have shared in the construction of this book, we acknowledge the pleasure of working with them and the stimulus they provide in their capacity to see a new edition as a new offspring and not just as a new dress for an existing one.

To the reader whose faith deserves more, we only wish we might have measured up in every detail; we can only acknowledge in real humility the support and confidence as expressed not only by use of previous editions, but also by expressions in word.

WALDO E. NELSON

# Contents

<b>THE FIELD OF PEDIATRICS</b>		
AN INTRODUCTION TO THE MEDICAL PROBLEMS OF INFANTS AND CHILDREN .....	1	
<i>Waldo E. Nelson</i>		
Problems of Various Age Periods ....	4	
The Pediatrician and His Patient ...	10	
<b>GENERAL FACTORS IN THE CARE AND EVALUATION OF CHILDREN</b>		
PHYSICAL GROWTH AND DEVELOPMENT .....	12	
<i>Harold C. Stuart and Stuart S. Stevenson</i>		
Growth of the Body as a Whole ....	13	
Osseous (Skeletal) Development ...	20	
Age Periods of Life before Maturity .	27	
Evaluation of Physical Status; Progress of Growth and Development .....	42	
TABLES OF NORMS FOR USE AS REFERENCE STANDARDS IN THE EVALUATION OF BODY MEASUREMENTS ....	47	
Techniques for Taking Measurements .....	48	
MENTAL AND EMOTIONAL DEVELOPMENT .....	62	
<i>Milton J. E. Senn</i>		
Heredity and Environment .....	62	
Reflex Actions and Learning .....	63	
Sensory Development .....	64	
Speech .....	65	
Emotional Development .....	65

# CONTENTS

XV

Pneumothorax and Pneumomediastinum .....	328
Lobar Emphysema .....	329
Lung Cysts .....	329
Disturbances of the Digestive System ..	330
Vomiting .....	330
Thrush .....	330
Constipation .....	330
Meconium Plugs .....	331
Meconium Bodies .....	331
Meconium Ileus .....	331
Meconium Peritonitis .....	332
Jaundice in the Newborn Infant ...	332
Disturbances of the Blood .....	335
Anemia in the Newborn Infant ....	335
Hemorrhage in the Newborn Infant	336
Disturbances of the Genitourinary System .....	337
Bilateral Renal Agenesis .....	337
Urinary Tract Infections .....	338
Disturbances of the Cranium .....	338
Craniotabes .....	338
Disturbances of the Skin .....	338
Localized Skin Defects .....	338
Erythema Toxicum .....	338
Milia .....	339
Impetigo Neonatorum .....	339
Pemphigus Neonatorum .....	339
Paronychia .....	339
Mastitis Neonatorum .....	340
Disturbances of the Eye .....	340
The Umbilicus .....	340
Anomalies .....	340
Tumors .....	341
Hemorrhage .....	341
Granuloma of the Umbilicus .....	341
Infections of the Umbilicus .....	341
Umbilical Hernia .....	341
METABOLIC DISTURBANCES .....	342
Transitory Fever of the Newborn ...	342
Edema .....	342
Tetany .....	342
DISTURBANCES OF THE ENDOCRINE SYSTEM .....	343
INFECTIONS OF THE NEWBORN .....	344
Escherichia Coli Infections .....	344
Staphylococcal Infections .....	344
Diarrhea in the Newborn .....	346
Neonatal Infection Due to Listeria Monocytogenes .....	347
Coxsackie Virus Infection in the Newborn .....	348
Herpes Simplex of the Newborn Infant .....	348

## UNEXPECTED SUDDEN DEATH

UNEXPECTED SUDDEN DEATH .....	350
<i>Sydney S. Gellis</i>	

## NUTRITIONAL DISTURBANCES

Malnutrition .....	352
<i>Waldo E. Nelson</i>	
Obesity .....	354
Nutritional Edema .....	356

Kwashiorkor .....	357
Vitamin A Deficiency .....	360
<i>Josef Warkany</i>	
Vitamin B Complex Deficiency ....	363
Scurvy .....	368
Rickets of Vitamin D Deficiency ....	371
Tetany of Vitamin D Deficiency ....	378
<i>Waldo E. Nelson</i>	
Vitamin K Deficiency .....	379
<i>Sydney S. Gellis</i>	

## INFECTIOUS DISEASES

INFECTION, IMMUNITY AND ALLERGY IN RELATION TO PEDIATRICS .....	381
<i>Charles A. Janeway</i>	
Pediatric Immunology .....	382
CLINICAL USE OF THE MICROBIOLOGY LABORATORY .....	384
<i>T. F. McNair Scott and Earle H. Spaulding</i>	
SELECTION OF ANTIMICROBIAL AGENTS BY LABORATORY MEANS .....	395
<i>Earle H. Spaulding</i>	
ISOLATION MEASURES FOR INFECTIOUS DISEASES .....	397
<i>Waldo E. Nelson</i>	
BACTERIAL INFECTIONS .....	401
STREPTOCOCCAL INFECTIONS .....	401
General Considerations .....	401
<i>Armine T. Wilson</i>	
Scarlet Fever .....	404
<i>William L. Bradford</i>	
Erysipelas .....	410
Diphtheria .....	411
Pertussis .....	420
Parapertussis .....	424
Meningitis .....	424
Tetanus .....	432
Bacillary Dysentery .....	434
Typhoid Fever .....	437
Salmonella Infections .....	442
Brucellosis .....	445
Tularemia .....	447
Tuberculosis .....	449
<i>Robert H. High and Waldo E. Nelson</i>	
Intrathoracic Tuberculosis .....	453
Extrathoracic Tuberculosis .....	466

SPIROCHETAL INFECTIONS .....	472
Syphilis .....	472
<i>Katharine Dodd</i>	
Leptospirosis .....	480
Infections Transmitted by Rat Bites .	481

# THE DIGESTIVE TRACT

THE ORAL CAVITY .....	619
<i>Julius B. Richmond, Maury Mas-</i>	
<i>sler and Isaac Schour</i>	
DISTURBANCES OF THE TEETH .....	620
Disturbances in Growth .....	620
Disturbances in Calcification .....	622
The Teeth in Dietary Deficiencies ..	622
Disturbances in the Eruption of Teeth	623
Disturbances in Attrition of Teeth ..	625
Dental Caries .....	625
Periapical Infection .....	626
DISTURBANCES OF THE FACE AND JAWS ..	627
Malocclusions of the Teeth .....	627
Facial Asymmetry .....	628
Fractured Incisors .....	628
Cleft Lip and Cleft Palate .....	628
Palatopharyngeal Incompetence ....	630
Hypoplasia of the Mandible .....	631
DISEASES OF THE GUMS AND GINGIVAE ..	632
Lateral Abscess .....	632
DISEASES OF THE ORAL MUCOSA .....	633
Herpetic Stomatitis .....	633
Other Aphthous Lesions .....	633
Thrush .....	633
Noma .....	634
DISTURBANCES OF THE LIPS .....	634
Fissures .....	634
Herpes Simplex .....	635
Allergic Eruptions .....	635
Mucous Retention Cyst .....	635
THE TONGUE .....	635
Fissured Tongue .....	635
Black Hairy Tongue .....	635
Geographic Tongue .....	635
Tonguetie .....	636
Macroglossia .....	636
The Tongue in Systemic Disturbances	636
Trauma .....	637
SALIVARY GLANDS .....	637
Enlargements of the Salivary Glands	637
Suppurative Parotitis .....	637
Recurrent Parotitis .....	638
Ranula .....	638
Mikulicz's Disease .....	638
TUMORS OF THE NECK .....	639
<i>Julius B. Richmond</i>	
Thyroglossal Duct Cyst .....	639
Branchial Cleft Cyst .....	639
THE ESOPHAGUS .....	639
<i>Paul H. Holinger</i>	
Congenital Anomalies .....	640
Acquired Diseases .....	643
Foreign Bodies in the Esophagus ...	645
THE GASTROINTESTINAL TRACT .....	647
DIGESTIVE DISTURBANCES .....	647
Anorexia .....	647
<i>Waldo E. Nelson</i>	
Vomiting .....	647
Normal and Abnormal Stools .....	650
Constipation .....	652
Encopresis .....	654
Diarrheal Disorders .....	655

THE STOMACH AND INTESTINES .....	658
DISORDERS OF THE STOMACH .....	658
Malformations and Malpositions of	
the Stomach .....	658
Inflammation of the Gastric Mucosa .	662
Gastric Dilatation .....	662
Gastric Hemorrhage .....	663
Neoplasms of the Stomach .....	663
Foreign Bodies in the Stomach and In-	
testines .....	663
Gastric Perforation .....	663
Bezoars .....	664
INTESTINAL DISORDERS .....	664
Malformations and Malpositions of	
the Intestines .....	664
Intestinal Obstruction .....	665
Diverticulosis and Diverticulitis ....	669
Peptic Ulcer .....	671
Regional Enteritis .....	671
Pneumatosis Intestinalis .....	672
Megacolon .....	673
<i>Norman Kendall</i>	
Appendicitis .....	676
<i>W. Emory Burnett</i>	
Mesenteric Lymphadenitis .....	678
<i>Waldo E. Nelson</i>	
Chronic Colitis .....	679
ANUS, RECTUM AND SIGMOID .....	680
<i>Harry E. Bacon</i>	
Malformations of the Anus .....	680
Malformations of the Rectum .....	681
Fissure in Ano .....	682
Pruritus Ani .....	683
Prolapse and Procidentia of the Rec-	
tum and Sigmoid .....	683
Anorectal Abscesses .....	683
Fistula .....	684
Hemorrhoids .....	684
Neoplasms .....	684
Congenital Dimples, Sinuses, Cysts	
and Tumors of the Sacrococcy-	
geal Region .....	685
PERITONEUM AND ALLIED STRUCTURES	686
Malformations of the Peritoneum ...	686
<i>Waldo E. Nelson</i>	
Ascites .....	686
Peritonitis .....	686
<i>W. Emory Burnett</i>	
Tumors of the Peritoneum and Mes-	
entery .....	689
<i>Waldo E. Nelson</i>	
Hernias and Hydrocele .....	690
THE LIVER .....	693
<i>Milton Rapoport</i>	
TESTS OF LIVER DISTURBANCES AND	
FUNCTION .....	697
Tests not Measuring Derangement of	
Liver Function .....	697
Tests Measuring Functional Capacity	697
Biopsy of the Liver .....	700

HEPATIC DISORDERS .....	700	Retropharyngeal Abscess .....	753
Circulatory Disturbances .....	700	Peritonsillar and Retrotonsillar Abscesses .....	754
Jaundice .....	700	Sinusitis .....	754
Infections .....	704	General Considerations of Chronic Infections of the Upper Respiratory Tract .....	756
Indian Childhood Cirrhosis .....	711	Chronic Rhinitis .....	756
<i>S. T. Achar</i> .....		Chronic Pharyngitis .....	757
Cysts of the Liver .....	712	Tonsils and Adenoids .....	757

# THE CARDIOVASCULAR SYSTEM

THE HEART AND CIRCULATION IN HEALTH AND DISEASE .....	819
<i>Samuel Kaplan and Robert A. Lyon</i>	
CONGENITAL HEART DISEASE .....	839
CONGENITAL CARDIAC DISEASE WITH CYANOSIS .....	842
Tetralogy of Fallot .....	842
Pulmonary Atresia .....	848
Tricuspid Atresia .....	848
Eisenmenger Syndrome .....	849
Transposition of the Great Vessels (Arteries) .....	851
Ebstein's Disease .....	852
Truncus Arteriosus .....	853
Single Ventricle .....	854
Aortic Atresia .....	854
Dextrocardia with Situs Inversus ...	855
Isolated Dextrocardia .....	855
Levocardia with Situs Inversus .....	855
Pulmonary Arteriovenous Fistula ...	855
Ectopia Cordis .....	856
Diverticulum of the Left Ventricle ..	856
CONGENITAL HEART DISEASE WITH LITTLE OR NO CYANOSIS .....	856
Ventricular Septal Defect .....	856
Atrial Septal Defect .....	859
Patent Ductus Arteriosus .....	863
Aorticopulmonary Septal Defect ....	866
Fistula of a Coronary Artery .....	866
Ruptured Sinus of Valsalva .....	866
Pulmonary Stenosis (with Normal Aortic Root) .....	866
Coarctation of the Aorta .....	870
Anomalous Pulmonary Venous Return ..	874
Congenital Aortic Stenosis .....	875
Congenital Mitral Stenosis .....	876
Anomalies of the Aortic Arch .....	877
Anomalous Origin of Coronary Arteries .....	877
Primary Pulmonary Hypertension ..	879
Marfan's Syndrome—Cardiovascular Manifestations .....	880
PRINCIPLES OF TREATMENT IN CONGENITAL HEART DISEASE .....	880
DISTURBANCES OF RATE AND RHYTHM OF THE HEART .....	883
Sinus Arrhythmia .....	883
Extrasystoles .....	883
Paroxysmal Tachycardia .....	884
Atrial Flutter .....	885
Atrial Fibrillation .....	885
Ventricular Fibrillation .....	886
Bradycardia .....	886
Heart Block .....	886
DISEASES OF THE ENDOCARDIUM .....	888
Acute or Malignant Endocarditis ...	888
Subacute Bacterial Endocarditis ....	888
Rheumatic Endocarditis .....	889
DISEASES OF THE MYOCARDIUM .....	893
Conditions Causing Myocardial Damage .....	893
Congenital Anomalies .....	895
Other Myocardial Diseases .....	896
Treatment of Cardiac Failure .....	897

DISEASES OF THE PERICARDIUM .....	899
Pericarditis .....	899
DISEASES OF THE BLOOD VESSELS .....	902
Aneurysms and Fistulas .....	902
Frostbite .....	902
Embolism .....	902
Thrombosis .....	903

RHEUMATIC FEVER .....	903
<i>Ann G. Kuttner</i>	

## DISEASES OF MESENCHYMAL TISSUES

RHEUMATOID ARTHRITIS .....	915
<i>Ralph J. P. Wedgwood</i>	
ANAPHLACTOID PURPURA .....	920
DERMATOMYOSITIS .....	922
SYSTEMIC LUPUS ERYTHEMATOSUS ....	925
PERIARTERITIS NODOSA .....	927
SCLERODERMA .....	928
MORPHEA .....	928

## DISEASES OF THE BLOOD

DISORDERS OF RED BLOOD CELLS .....	930
<i>Nathan J. Smith, Victor C. Vaughan, III, and Louis K. Diamond</i>	
THE ANEMIAS .....	933
Anemias Due to Inadequate Production of Erythrocytes or Hemoglobin ...	934
Congenital Hypoplastic Anemia ....	934
The Aplastic Anemias .....	935
Anemia of Chronic Infection .....	937
Anemia of Chronic Azotemia .....	938
The Megaloblastic Anemias .....	938
Anemia of Iron Deficiency .....	941
Anemias Due to Excessive Loss of Erythrocytes .....	943
Anemia Due to Acute Hemorrhage ..	943
Anemia Due to Chronic Hemorrhage ..	944
Hemolytic Anemias .....	944
POLYCYTHEMIA, ERYTHROCYTOSIS AND ERYTHREMIA .....	962
DISORDERS OF THE LEUKOCYTES .....	963
Agranulocytosis .....	964
Periodic Neutropenia .....	965
Chediak-Higashi Syndrome .....	965
The Leukemias .....	966
DISEASES OF THE BLOOD ASSOCIATED WITH DEFECTS IN HEMOSTASIS ...	970
Laboratory Tests Useful in the Study of Patients with a Bleeding Tendency .....	972
DEFECTS OF HEMOSTASIS IN SMALL VESSELS .....	973
Other Vascular Defects Associated with Bleeding Tendency .....	973
Idiopathic Thrombocytopenic Purpura .....	974
Thrombotic Thrombocytopenic Purpura .....	976
Thrombocytopenia in the Newborn ..	976
Thrombocytopenia and Giant Hemangioma .....	977

DISTURBANCES OF THE MECHANISM FOR CLOTTING .....	977
The Hemophilias .....	977
Deficiencies in Prothrombin and Accessory Factors .....	980
Disorders Involving Fibrinogen and Fibrin .....	982

### THE SPLEEN

THE SPLEEN .....	985
<i>Nathan J. Smith</i>	
Congestive Splenomegaly .....	986
Splenic Cytopenia .....	988
Infarction of the Spleen .....	989

### THE LYMPHATIC SYSTEM

DISEASES OF THE LYMPH VESSELS .....	990
<i>Nathan J. Smith, Victor C. Vaughan, III, and Louis K. Diamond</i>	
DISEASES OF THE LYMPH NODES .....	991
Lymphadenitis .....	991
Neoplasms of Lymph Nodes .....	992
Hodgkin's Disease .....	994

### THE THYMUS GLAND

THE THYMUS GLAND .....	997
<i>Waldo E. Nelson</i>	

### DISTURBANCES OF CELLULAR LIPID METABOLISM AND RELATED CONDITIONS

DISTURBANCES OF LIPID METABOLISM:	
THE LIPIDOSES .....	999
<i>Sydney S. Gellis</i>	
Gaucher's Disease .....	999
Niemann-Pick Disease .....	1000
Xanthomas of the Skin .....	1001
DISEASES OF THE RETICULOENDOTHELIAL SYSTEM: THE RETICULOENDOTHELIOSES .....	1002
Hand-Schüller-Christian Syndrome ..	1002
Letterer-Siwe Disease .....	1003
Eosinophilic Granuloma .....	1004

### THE GENITOURINARY SYSTEM

CLINICAL ASPECTS OF RENAL PHYSIOLOGY .....	1005
<i>Philip L. Calcagno</i>	
Glomerular Filtration .....	1006
Tubular Reabsorption .....	1007
Tubular Excretion .....	1008
Special Clearances .....	1008
Acid-Base Regulation .....	1008
Renal Function in Young Infants ...	1009

URINE AND URINATION .....	1010
<i>Mitchell I. Rubin</i>	

DIAGNOSTIC TESTS USED IN THE STUDY OF KIDNEYS .....	1012
DISORDERS OF URINARY SECRETION ...	1014
DISTURBANCES IN QUANTITY OR EXCRETION OF URINE .....	1014
Oliguria .....	1014
Retention of Urine .....	1015
Polyuria .....	1015
Frequent Urination .....	1015
Incontinence of Urine .....	1015

Enuresis .....	1015
<i>Sherman Little</i>	

ALTERATIONS IN COMPOSITION OF URINE .....	1018
<i>Mitchell I. Rubin</i>	

Albuminuria .....	1018
Glycosuria .....	1019
Pentosuria .....	1020
Galactosuria .....	1020
Lithuria .....	1020
Indicanuria .....	1020
Lipuria .....	1020
Acetonuria .....	1020
Hematuria .....	1020
Ammoniacal Urine .....	1021

ABNORMAL PIGMENTS IN THE URINE ...	1021
Abnormally Colored Urine .....	1021
Hemoglobinuria .....	1021
Paroxysmal Hemoglobinuria .....	1022
Melanuria .....	1022
Bile Pigments in the Urine .....	1022

MALFORMATIONS OF THE URINARY TRACT .....	1022
--	------

MALFORMATIONS OF THE KIDNEY, URETERS AND BLADDER .....	1023
Renal Agenesis and Hypoplasia ....	1023
Polycystic Disease of the Kidneys ...	1024
Solitary Renal Cyst .....	1024
Exstrophy of the Bladder .....	1024
Patent Urachus and Urachal Cyst ..	1025
Malformations Producing Obstruction to the Urinary Flow .....	1026
Displacement of the Kidney .....	1030

INFECTIONS OF THE URINARY TRACT ..	1030
Pyelonephritis, Pyelitis .....	1030
Perinephritis .....	1034

DISTURBANCES OF THE KIDNEY .....	1035
Nephritis .....	1035
Nephrotic Syndrome .....	1044
Tuberculosis of the Kidney .....	1052
Hemorrhagic Infarction of the Kidney	1053
Renal Calculus .....	1054

DISTURBANCES OF THE URINARY BLADDER .....	1055
Vesical Calculus .....	1055
Foreign Bodies in the Bladder .....	1055
Cystitis .....	1055
Tuberculosis of the Bladder .....	1055
Spasm of the Bladder .....	1056

MALFORMATIONS AND DISEASES OF THE MALE AND FEMALE GENITAL ORGANS .....	1056
Adherent Prepuce .....	1056
Phimosis .....	1056
Paraphimosis and Strangulation of the Penis .....	1056

Abnormal Size of the Penis ..... 1057

Balanoposthitis ..... 1057

Malformations of the Urethra ..... 1057

Inflammation of the External Urethral  
Orifice ..... 1058

Urethritis ..... 1058

Foreign Bodies in the Urethra, Includ-  
ing Urethral Calculus ..... 1058

# The Field of Pediatrics

## AN INTRODUCTION TO THE MEDICAL PROBLEMS OF INFANTS AND CHILDREN

No field of specialized medicine has a broader scope, greater responsibilities or greater possibilities than has pediatrics. One important fact sets it apart from other divisions of medicine: it is chiefly concerned with the *continued* growth and development of its subjects.

The goal in the medical management of the child is to permit him to come into adulthood at *his* optimal state of development, physically, mentally and socially, so that he can compete at *his* most effective level. The physician who cares for children must of course be familiar with the illnesses and psychologic disturbances peculiar to infants and children and their reactions to them. But he must also know what constitutes adequate achievement at successive age levels for children of different body types and capabilities, with or without obvious physical or mental handicaps. This, the individualization of the child, is the essence of pediatric practice.

In the span of years from birth to maturity, when growth is complete, the physician must deal with a subject who is so different at various stages that it might almost seem he had been several distinct individuals. The characteristics of these stages are not sharply demarcated time-wise, but blend from one into the next. Nevertheless the general pattern of each stage is sufficiently different from each of the others to consider them separately. These stages, the general characteristics of which are listed in Table 5 (p. 26), are (1) the intrauterine period; (2) the neonatal period, the first four weeks of life; (3) the period of infancy and of rapid growth, the first two years; (4) the preschool period, two to six years of age; (5) the period of mid-childhood or the so-called school period, six to ten years of age for girls and six to twelve years for boys; (6) the prepubescent period, ten to twelve years of age for girls and twelve to fourteen years for boys; and (7)

the pubescent and postpubescent periods (adolescence), twelve to eighteen years of age for girls and fourteen to twenty years for boys. In the strict sense the process of birth should also be considered a separate period, since injury of the infant at this time may have serious and even permanent effects.

A number of factors are responsible for variations in the clinical manifestations of disease caused by identical etiologic agents in infants or children and in adults. These differences are implied by the phrase that "the child is not a little man" and include variations in anatomic, physiologic, pathologic and immunologic patterns. In most instances there is a direct relation to age: the younger the child, the more marked are the differences; conversely, as the child approaches maturity, the more do physical disturbances simulate those of adults.

*Anatomic variants*, such as the relative thinness of the chest wall, the more horizontal position of the heart, and the open sutures of the cranial bones in infants, are responsible for physical findings which both in health and in disease differ from those related to the same structures in adults.

*Physiologically*, the relatively greater nutritional needs of infants (calories, proteins, minerals, vitamins and water) reflect the requirements for growth in excess of those for basal functions and physical activity. During illness the infant and small child have less capacity than the adult to maintain homeostasis. Thus the infant with a diarrheal disturbance is in a more precarious position than an older child because of the greater rapidity with which severe disturbances of water and electrolyte metabolism develop.

*Pathologically*, the differences appear to be mainly those related to the effects of injurious agents upon growing tissue in contrast to those upon mature tissue. Thus vitamin D-

deficient rickets and infantile scurvy have quite different clinical patterns in infancy than they do in later childhood.

*Immunologically*, the infant is, in general, more susceptible and less resistant to infection. There are exceptions: to a few infections the infant inherits a limited, short-lived immunity from the mother.

*Mental development and psychologic development* provide the most important measures of the adequacy of growth during infancy and childhood. Training, education and molding of the child's personality determine the level of ultimate achievement. It is understandable that parent education, child guidance and psychiatry have become increasingly important in the medical care of children.

Pediatrics as a specialty of medical practice had its inception in this country in the latter part of the nineteenth century. Since that time there have been great changes in the medical problems of children and consequently in pediatric practice. In 1900 the death rate for infants under one year of age was in the range of 200 per 1000 live births; in 1954 it was only 26.6 for the country as a whole, and in some areas significantly lower. The death rates in the subsequent years of childhood have been reduced to an even greater extent. The notable reduction in the incidence of serious illness is attributable to a number of factors, some general, some spe-

cific. Improvements in the socio-economic status of general populations as represented by better housing and more adequate diets have been factors in increasing resistance to disease. Specifically, prevention of such diseases as diphtheria and smallpox and modification of others such as measles have been accomplished by vaccines and immune serums. Educational measures have been highly effective in the prevention of other diseases; these include isolation of tuberculous patients and the sterilization of milk formulas for infant feeding; the latter is the most important factor in the reduction of infant mortality in the postnewborn period. More recently the availability of effective sulfonamides and antibiotics has made possible successful therapy of many otherwise fatal infections. Such nutritional disturbances as rickets, scurvy, pellagra and nutritional edema have been largely eradicated in this and many other countries by general and specific health measures and can be controlled by appropriate measures in the remainder. The differences in the mortality rates of infants and small children between countries with marked variations in living standards are shown in Figure 1. Much of the credit for the great improvement in child health must be given to research, and continued improvement can be expected from further investigation in the fields of microbiology, chemistry, genetics and child be-

Department of Health, Education, and Welfare, Social Security Administration, Children's Bureau. Based on Data from the National Office of Vital Statistics.

Causes of death listed are the 10 leading causes in any one of the years specified. Titles of the causes named are those of the Sixth Revision of the International Lists for 1950 and 1955; of the Fifth Revision for 1940; of the Fourth Revision for 1930; and of the Third Revision for 1920. All rates are unadjusted for differences in classification of causes of death in successive revisions of the Lists.

havior by persons dedicated to a more adequate understanding of the child and of his environment.

The concept of the field of pediatrics which certain persons hold, even some closely connected with medical circles, is a limited one. To some the practice of pediatrics is essentially infant feeding; to others it is the management of the ills of the first two or three years of life; to still others it is the practice of preventive medicine; and to a few it is simply the management of behavior disorders. It is all these and more. Concern for the child must antedate conception and extend through the final phases of growth in the period of adolescence. Care of the unborn child is provided by adequate supervision of the pregnant woman, and obstetric care at the time of delivery is directly reflected in the welfare of the infant. The neonatal period is the most hazardous period of life and presents problems that never arise again. Infancy represents the period of most rapid growth. This is the time when the infant is completely dependent on others for all phases of his care; when he is not only more susceptible to infections and nutritional disturbances, but often has a pattern of response to them which differs from that of later years. As the age of infancy is passed and the pre-school, prepuberty and adolescent ages are attained, the child assumes increasing responsibility for his own care, but intelligent and understanding pediatric supervision can continue to be an important aid. Surveys of children in all economic strata reveal a high incidence of nutritional and physical disturbances and of psychologic difficulties which are remedial and, more important, preventable.

## PROBLEMS OF VARIOUS AGE PERIODS

**Advisability of Parenthood** (see also pp. 247 and 1136). Young persons contemplating marriage, and couples who have had one or more defective offspring, often seek advice concerning the advisability of future parenthood. The increasing tendency for some degree of civil control over physical and mental fitness for marriage and parenthood will probably result in more frequent consultations. The physician who assumes such a responsibility must be well informed concerning the medical and legal aspects of fitness for parenthood. The problem involves the factors of genetic patterns and of physical, mental and moral fitness of the prospective parents. Moral fitness constitutes the most difficult

problem and, unless legal measures can be taken, is not controllable beyond the cooperation of the prospective parents.

**Prenatal Factors.** During pregnancy the mother's health is the most important factor determining whether the fetus will be carried to term and delivered in a viable, healthy condition. Adequate nutrition, properly balanced rest and exercise, and freedom from worry are essential to ensure this goal. Specific disturbances of the mother may affect the fetus, such as German measles during the first trimester, syphilis, toxoplasmosis, isoimmunization and diabetes mellitus. Regular prenatal visits to the physician have had a distinct effect in the reduction of both maternal and infant mortality. These visits should also be used to counsel the parents concerning the care of the newborn infant. Many problems of early infancy could be averted if prospective parents had a more adequate concept of infant care and especially of how simple and natural it can and should be.

**Natal Factors.** Every infant should be delivered by an adequately trained physician. The fact that more than 10,000 infant deaths a year are directly attributable to birth injuries and that many other infants are crippled for life illustrates the need for improvement in the technique of obstetric care. The choice and use of sedatives and anesthetics, the mechanics of delivery, including the improper use of forceps as well as failure to use them at appropriate times, and the management of the infant immediately after birth are factors which affect the offspring. Failure to clear the air passages of mucus and amniotic fluid contents, damage resulting from manual and mechanical attempts at resuscitation, failure to prevent chilling the infant, and nonantiseptic technique are also important factors.

**Neonatal Factors** (p. 28). During the neonatal period the infant must make adjustments to extrauterine existence. The difficulties are illustrated in part by the exceedingly high mortality rate and by the multiplicity of physical disturbances, many of them characteristic of this period.

Prematurity (pp. 286 and 306) is the most important problem of the neonatal period. During the first month of life infants born prematurely account for almost half of the total number of deaths. The smaller the infant, the less his chance of survival. However, weight of the infant at birth is not the sole factor determining survival. Toxemia or other

illness of the mother, the physical condition of the infant and the quality of his care beginning immediately after birth are of the greatest importance.

Injuries at birth and congenital malformations are important causes of crippling and death. Although certain injuries appear to be unavoidable, and others justifiable to save the mother's life, better obstetric care should result in a further reduction in neonatal mortality. Many congenital malformations are incompatible with life, but early recognition and treatment of certain ones will result in an increased saving of life.

Though acquired disease is relatively less important as a cause of death in the neonatal period, some idea of its actual importance may be obtained from the fact that in 1949 almost 4000 deaths of newborn infants were

attributed to respiratory and gastrointestinal diseases. This number represents more than one fifth of all deaths due to these causes in the first year of life.

The mortality rates of any age period do not completely reflect the relative importance of its various medical problems. Some deaths in age periods beyond the neonatal and many instances of prolonged illness and of persistent physical and mental disabilities have their origin in the perinatal period.

**Infancy Factors.** Infancy is the period of most rapid extrauterine growth. Adequate growth and development, both physical and mental, are essential to normal infancy, and the rates of development constitute the best measures available for evaluation of the infant's status. During most of this period the infant is dependent on others for mainte-

FIG. 2. Infant mortality rates by age, 1916-55. (U. S. Birth Registration area.) (From Children's Bureau Statistical Series No. 50.)

FIG. 3. Childhood Mortality, 1900-55. (U. S. Death Registration area.) (From Children's Bureau Statistical Series, No. 50.)

nance. Walking and eating alone are usually achieved by the latter part of this period. Nutritional deficiencies are thus particularly likely to be the fault of the person who designs the diet or feeds the infant. Likewise, infections are brought to the infant in contrast to his going to them, as he is more likely to do in the toddler and school years. These factors are important, since they make preventive measures more effective and simpler to apply during infancy. The infant is not only more susceptible to infections and nutritional disorders, but also in general has less resistance to them, and for many of them has clinical patterns which are distinctive. He has some degree of passive immunity during the first four to six months of life for measles, diphtheria, scarlet fever and poliomyelitis if the mother has had them, but not for the other common contagious diseases or for pneumococcal, staphylococcal, streptococcal or influenza infections.

The mortality rate for the second to the twelfth months of the first year of life is less than that for the first month alone (Fig. 2).

Analyses of the mortality rates reveal that infant death rates are consistently higher for males than for females in all races, higher in the other races than in the white race, higher for infants born in the winter months than in other seasons of the year, and higher for infants born in rural areas than in cities. It has been demonstrated that the high rate of infant mortality among families of low economic status can be reduced by education of the mother in the technique of infant care. So-called well-baby clinics or stations have been significant in dispensing such information and may be one of the factors responsible for the mortality rate being lower for infants in urban than in rural areas. Intelligence, education, housing, and economic level are probably more important than racial factors.

**Preschool Age Factors.** This period, the earlier part of which is termed the toddler age, is a safer one than infancy. The preschool age is important because the health of the child at this period is definitely reflected in the school years. Emphasis should be placed on normal living, with ample opportunity for the child to explore and become acquainted with his expanding world. The "guiding hand," which seems to be a necessity in the complexity of modern living, must lead and restrain, but should not prohibit the child from developing his own natural pattern.

Adequate nutrition, immunization against the preventable diseases, education in the avoidance of the nonpreventable ones and in the prevention of accidents, early and adequate medical care for disease, and counseling in family living are the important factors. The goal is a physically sound, mentally alert,

socially adjusted candidate for entrance to school.

**School Age Factors.** The total mortality for the period from five through fourteen years of age is less than for the period of one through four years of age. Of particular interest is the reversal in recent years of the relative positions of infectious and cardiovascular diseases and cancer as causes of death (Fig. 6).

The expanding environment of the child during these years provides him with increasing opportunities for mental and social growth. Wise parents will permit their child the sense of self-determination without eliminating the sense of a haven at home where support will always be available when needed and, of equal importance, where confidence and love are continually present. Many of the preventable cases of juvenile delinquency

## INFANT MORTALITY, BY AGE, UNITED STATES, 1954

FIG. 5. Infant mortality by age, United States, 1954. (From Children's Bureau Statistical Series, No. 42.)

have their inception during these years. It is the wise physician who can assist in the problems of adjustment within the child's various groups—his family, school and playmates.

The goal is a physically sound, mentally alert, socially adjusted preadolescent child.

**Adolescent Factors** (see also p. 147). During this period there are tremendous physical and psychologic changes which under natural situations should occasion no difficulties. Unfortunately, "natural situations" prevail too infrequently. The physician who guides a child through the preadolescent years and understands him should have distinct advantages as the medical advisor for the adolescent years. But this can be true only if he understands the problems of this period and will give the necessary time to each of his adolescent patients.

The physical disturbances include such

chronic infections as dental caries, otitis media, tuberculous and nontuberculous pulmonary infections, rheumatic carditis, osteomyelitis, gonorrhea and syphilis; nutritional disturbances which range from undifferentiated malnutrition through the various specific nutritional deficiency diseases; and endocrine disturbances.

The onset of puberty and the rate of development during adolescence vary considerably from child to child. The rapidity of growth at this time makes the child especially vulnerable to detrimental influences, and one may expect that physical disturbances will have more significant effects upon growth and development than they do in the years of relatively slower growth between infancy and puberty.

The working adolescent child presents special problems. In part these are being met

by special legislation; but many factors center in the home and in recreational and educational facilities, besides those concerned with the type and place of work.

Health education, which should include adequate sex education, may be more effective at this age than at any other time of life. Behavior and social problems constitute a large part of adolescent care. Though emphasis should be placed on preventive measures in the preadolescent period, many maladjusted children will continue to require treatment. The problem of juvenile delinquency is especially urgent. Special clinics for adolescent children are doing much to meet the needs of this age group, and their extension is to be encouraged, as are increased provisions for vocational guidance.

**Handicapped Children.** Children with physical and mental handicaps present special

problems. The term "handicapped" implies a physical or mental defect not compatible with normal activity or achievement. Formerly much attention was centered on the orthopedic cripple, but in recent years interest has broadened to include almost all types of defects. Special attention is required for children with hearing, speech and sight defects, with cardiac disease, with tuberculosis, with orthopedic defects of peripheral and central origin, with mental retardation and with psychotic disorders. In addition to specialized medical attention, there is need for special classes, schools and institutions.

Initially, the problem is one of detection. Then the child must be thoroughly evaluated physically, mentally and psychologically. The family situation must also be appraised. All this usually requires a "team" approach. But the child and his family must have a single

FIG. 6. Childhood (1-14 years) mortality. Main causes by Sixth Revision of the International Lists, United States, 1945 and 1955. (From Children's Bureau Statistical Series, No. 50.)

physician who assumes over-all responsibility and directs the program for the child. "Handicapped" children and their families must be treated realistically. Everything should be done which will provide the child with his optimal opportunities, but neither the child nor his family should be led to expect something which is impossible. Only to the extent that the "handicapped" child can be brought to a stage of independence compatible with his handicap can success be said to have been attained.

**Community Responsibility.** Health is a community problem. This does not imply that the individual must not assume personal responsibility or that the practice of medicine should not be a private enterprise. Certain aspects of health, such as control of communicable diseases, become the responsibility of the community merely for the protection of the uninfected. But other aspects are humanitarian ones. In a true democracy, health services should be the right of each child.

In his presentation before the White House Conference on Children in a Democracy in 1940, A. Graeme Mitchell stated the problem simply and clearly:

... It is obvious that proper physical and mental health cannot be expected unless there are good housing, proper clothing, satisfactory food, happy family life, facilities for recreation and education. . . . With heightened speed during the past decade, knowledge of the health needs of children has been acquired. . . . There is an obvious inequality in distribution of medical care in economic groups and in communities.

... Some families are able through their own resources to furnish good housing, clothing, food, recreation, education, and medical care to their children. Other families must face . . . unpredictable emergencies . . . which [cause] health as well as other essentials of family life to suffer. Then there is the group who are unable through their own resources to provide even the minimum needs.

... These inadequacies and many others constitute failure to protect the children of this democracy. All these inequalities are the concern of all of us—of the local community, the State, and the Nation.

**Individuality of the Child.** In the enthusiasm of solving a medical problem the physician often fails to recognize that he is dealing with a child who is sick rather than with a physical illness per se. Often the psychic disturbances of illness are as great as or greater than the physical ones. This situation is as true for infants and children as for adults. Thus in pediatric practice, interest should be primarily in the child and secondarily in his disease. Every disturbance should be viewed from the standpoint of its

effect upon the child and why it has such an effect.

## THE PEDIATRICIAN AND HIS PATIENT\*

Every child is an actor in a play; each phrase or deed is understood only as a part of his total role, and that role is meaningless except as a part of the total drama.

This role was pressed into his tiny hands long before he stepped upon the stage. Months before he was born, parents, relatives and neighbors "hoped it would be a boy" or "hoped it would be a girl"—lacking the courtesy to wait upon his arrival before deciding the part he must play. Indeed, his role goes farther back to the dreams, the tragedies, the triumphs of the early years of his parents. Who of us has not mended the disappointments of youth and adulthood with the promise that this child "will live it differently"? The role he is to play is often cast down to the last dotting of the "i" or crossing of the "t."

Children as actors differ markedly in what they do with their roles. Many, in comfortable security, accept and play the role as given to them. Many are tragically unsuited for the part they are expected to play—of the wrong sex, too intelligent, too retarded, too individualistic, too dependent, too frail for the titanic struggle or too eagerly adventuresome for a part that calls for docility. Some children forever grope in confusion to find the meaning of their roles, whereas others in ritualistic manner grow, go to school, work, marry, have children, amass a fortune, die—without ever having had the slightest idea of what it is all about. The pediatrician must understand these things and carefully assay the child's fitness to do what he is supposed to do.

Time should be taken to think of the family in its total setting. If the parents are over-anxious, mere irritation toward them accomplishes nothing. If the child is driven physically and mentally beyond his powers, the answer does not lie in exasperated denunciation, but rather in getting the family to assay its goals and values with more care. Every illness may be complicated—seriously so—by the family's call upon the child to be the Spartan or the dependent one. These compelling attitudes have a natural cause just as surely as do fever and pain.

It is important to know what the child means to each parent. Sometimes anxious

\* Originally written for the fourth edition by the late James S. Plant.

concern over his illness is a sort of emergency repair patch for a precariously thin marital situation. Just as often the physician will find a growing jealousy in one parent as the child absorbs the interest of the other. Some carry the care and expense of the child with poor grace; others glory in this and unwisely lavish too much in their joy of self-denial. An endless number of complaints about a child may mean that he has rudely broken in upon a "career" or the building of family fortunes.

The pediatrician may feel that these matters are none of his concern. But they are serious "complications" of every illness, and the basis of all sorts of pressing problems of child rearing that are brought to his office.

The pediatrician must also cultivate the practice of seeing the child alone and having him feel that his confidences are respected. The technique of the "own story" should be developed. This is a brief recapitulation of events, starting well behind the event under consideration. If one asks a child (or adult, for that matter) why he stole or played truant, he usually does not know. Many things we do are inexplicable as we look back upon them, but seemed reasonable when we did them. Thus the pediatrician must approach events as the child approached them. It is only as one sees what an act meant to the child at the time it was carried through that it can be understood.

The language of intelligence is words; the language of the emotions is the psychomotor tensions. One can tell a child that he has a fever; one has to show a child equanimity, courage, faith. The pediatrician cannot anxiously tell the parent to be calm, or hurriedly tell the child to be patient. We depend so much upon the written and spoken word that we fail to realize how utterly inadequate it is in the important field of the emotions. It is in the way that we talk, stand, walk, give advice that we transmit our most important messages.

In order to understand the activities and

reactions of a child, the pediatrician must have or acquire three fundamental attributes:

1. *Everlasting patience.* The "ortho" tendency, the fundamental drive to right the ship, is strong in all of us. Giving the child time and freeing him from adult anxieties and meddlesomeness are extremely important.

2. *Faith in the child's ability to solve his own problems.* Enuresis is the child's problem, as is petty stealing, lying and a legion of other matters that the parents or teachers are feverishly trying to solve for the child. When once the pediatrician has really won the child's confidence, he must persistently show his faith in that child's own ability to work out whatever his problem may be. It is not so much the pediatrician's task to stop the child's temper tantrums as to give him a fair and objective picture of what happens if they are continued.

3. *Ability to see the problem through the child's own eyes.* This is not to excuse—but to understand. Until the pediatrician has seen what the child is trying to do, he is working in the dark. Problem children are not trying to create problems—but to solve them. As fever and pain are normal reactions of normal people to abnormal conditions, so lying and stealing and persistent bed-wetting and temper tantrums may be normal reactions of normal children to unusual or abnormal conditions. In each instance the child is trying in his own way to solve a problem in human relationships.

In all these matters the pediatrician is in a peculiarly difficult position. His age and position of authority lead the child to feel that he is "just another adult." Thus he invites those same reticences, rebellions and bombastic aggressions that forced the parents to bring the child to him. Yet unless he resolutely attempts to approach the problems of childhood on this broader and natural basis, he remains a specialist in the diseases of children, rather than a specialist for children.

WALDO E. NELSON

# General Factors in the Care and Evaluation of Children

## PHYSICAL GROWTH AND DEVELOPMENT

### GENERAL CONSIDERATIONS

A knowledge of the growth and development of the human organism from conception to maturity is of basic importance to the physician who would attempt to care for infants and children and to advise parents as to the normality of their progress. The basic goal of the fetus, the infant and the child is to grow and develop toward an adult maturity which will represent for him optimal health and physical and mental fitness. Success, even survival, is dependent upon continuous though diminishing parental care and guidance and a protective environment. This care and protection should be adapted to each child's needs and capabilities.

The term "growth and development" as used in pediatrics applies to all aspects of progress of the human organism from conception to maturity. "Growth" refers to the changes in size resulting from multiplication of cells or increase in intercellular substances, whereas "development" refers to the maturation of structures and functions associated with this progress. It is not possible to distinguish sharply between the terms "growth" and "development," but the conjoined expression suggests a broader scope and a more complex set of factors than either term alone. Furthermore, it is now widely accepted as denoting all the chemical, physical and psychologic processes responsible for the closely inter-related changes in the forms and functions of all the body tissues, as well as the increasing capacities and purposeful adaptations acquired in the progress toward maturity. Growth is more readily evaluated than is development, because physical measurements are easier to apply and interpret than functional tests, but the latter must not be neglected. They progress together, but at times there may be development with little increase in size, or rapid growth with little differentiation in structure or function. The cortical function-

ing of the brain, for example, progresses in complexity long after measurable growth has ceased.

The rapidity of development and growth of the fetus magnifies the effects of unfavorable environment during gestation. The first two to three months after conception, during which organic differentiation is accomplished from a single-celled ovum, is a particularly critical time when adverse influences may result in congenital malformations. An understanding of the etiology of congenital malformations thus demands knowledge of the growth and development of the fetus.

Almost all disease processes and many congenital defects may affect some phase of growth and development. Some diseases simply retard growth or delay development, and natural adaptations make possible full recovery of lost ground. Others cause local or widespread tissue damage, arresting or permanently ending growth in certain parts. For example, poliomyelitis may affect only an extremity; encephalitis may affect the brain and, through it, the entire organism. Deficiencies of specific nutrients, notably vitamin D, distort growth in a characteristic manner, leading to deformities and disproportions which may not be fully compensated after the deficiency has been corrected. Deficiencies or excesses of specific hormones lead to delayed growth, overgrowth or disproportionate growth, to retarded or advanced maturation, to mental retardation and physiologic aberrations, or to various combinations of these.

In planning for the needs of a child, whether for food, sleep, activity or psychologic management, it is important to know not only what he is like as an individual, but also to understand how rapidly and in what ways he is changing. A general outline can be given for the care of the average child at a given age, but the details of the advice for a particular child should be determined after study of his physical and mental attributes,

the course of his development, and the way in which he has responded to the care and feeding already provided.

Proper assessment of a child's growth and development is essential as a guide for treatment of disease or disability. The best possible progress for the child who has genetic or acquired handicaps is promoted in various ways, but principally by helping the parents to understand the particular needs of their child at each age and to protect him from unfavorable environmental influences.

Thus the infant or child must be considered in respect to norms which are specifically applicable only to a given age or stage of development and which have wide ranges of individual variability. The many attributes, weaknesses and needs which are especially important and often peculiar to children of a given age, but which differ from those of the preceding and following ages, must also be taken into account. The changing characteristics and needs are understandable only after study of the main trends of growth and development throughout infancy and childhood, and of the patterns of variability encountered among normal children.

## GROWTH OF THE BODY AS A WHOLE

Although growth occurs continuously from conception to full maturity, it is by no means uniform from period to period, nor does it progress haphazardly by frequent spurts and rests. There are minor irregular fluctuations, especially in gains in weight, but for the most part increments of growth in any dimension or part of the body occur at predictable periods in accord with a characteristic pattern. This pattern for most parts of the body involves two periods of rapid growth separated by one of relatively uniform and slower increase. Each period is characterized by an accelerating rate of increase to a maximum, followed by rapid deceleration and a leveling off to a relatively slow increase, or terminating altogether in the part or parts concerned. The first of these cycles of rapid growth completes its accelerating phase during fetal life, and the decelerating phase extends throughout much of the preschool age period. The second cycle starts in the prepuberal stage and spans much of the second decade, or the years during which adolescent changes are taking place, and tapers off to a cessation of growth at maturity.

Most tissues and parts of the body participate in the cycles of rapid growth, so that

the increases in any measurement tend to reflect the general pattern. Nevertheless there are notable differences in the magnitudes of growth increments and in the timing of changes in the different parts or tissues. The peak of growth in length in the fetal cycle, for example, occurs about the end of the second trimester of pregnancy, whereas the peak of gain in weight occurs just before term (Fig. 7). The accelerating phase of the adolescent cycle, in contrast, begins earlier and is relatively greater in magnitude for weight than for height (Fig. 8).

The period of relatively uniform and slow growth which separates the two cycles of rapid growth has certain characteristics of interest, as shown in Figure 8. The increments in weight tend to increase slightly during this

FIG. 7. Average increments in weight and length by trimesters during the prenatal and infant periods.

The data on growth in weight during the prenatal period are from Jackson (*Prenatal Growth of the Human Body*, Am. J. Anat., Vol. 9), and those on length from Hiss (*Unsere Körperform*, Leipzig, 1874), all adapted for this chart from figures by Feldman (*Ante-natal and Post-natal Child Physiology*, New York, Longmans, Green and Co., 1920). These data were obtained from a few cases at each age and from various sources, usually fixed specimens of calculated fetal age. They are used here since more accurate data do not appear to be available, and must be viewed from the standpoint of relative magnitude only.

The data on growth during infancy, in contrast, are from repeated measurements of the same group of living children studied in recent years by Stuart and his associates in Boston (derived from Table 9, p. 50). The columns for the fifth, sixth, seventh and eighth trimesters represent half of the 6 months' increments rather than actual 3 months' values. Although the true values for the prenatal increments of the latter group of infants would doubtless be higher than those portrayed, especially during the last trimester, it is clear that maximum growth in length occurs during the middle trimester of pregnancy, whereas that in weight occurs during the late fetal period.

FIG. 8. Average increments by years in principal body measurements.

All increments were derived by the difference between the medians at succeeding ages. Measurements were obtained from one group of children under 5 years of age in Boston, and from another after 5 years of age in Iowa. The data from which these increments were obtained and further information regarding their source are given in Tables 10 and 11 (pp. 52 to 56).

period, while those in height continue to decrease. This is due in large measure to a relative enlargement in certain parts of the skeleton as shown in chest circumference and, to some extent, to an increase in muscle mass and subcutaneous tissue. The changes are so gradual that they are not readily recognized, but the total effect is to make the ten-year-old child appear more robust than the five-year-old one. This change is reflected in improvement in muscle tone and ligamentous support and hence in posture and other features of body mechanics. The child who matures slower than the average causes concern to parents because he stands out in sharp contrast to the majority of his classmates.

Some parts or tissues of the body participate in only one of the two periods of rapid growth, and some follow a different pattern altogether (Fig. 9). For example, the brain grows rapidly during the first cycle and ceases growth before the second cycle begins. It has attained about 25 per cent of its adult size at the time of birth, when total body weight represents only about 5 per cent of adult weight. About 50 per cent of its postnatal growth occurs during the first year of life and nearly 20 per cent in the second year: hence the importance of damage to the brain in infancy and the interest in head circumference as a measure of progress at this period. The genital organs, by contrast, grow relatively slowly during the first ten years and rapidly during the second ten years. They increase considerably in size after growth of the body as a whole has ended. The rate of increase of lymphoid tissue is relatively rapid throughout the first decade; at ten years of age there is normally nearly double the amount of this tissue that there is at maturity. This unique pattern must be kept in mind when assessing tissues such as tonsils and lymph nodes in childhood.

The data on the weights of organs at various ages are inadequate to define individual growth curves. The standards used to represent normality are based of necessity on post-mortem measurements and hence are of doubtful reliability for normal living structures. The growth of the eye follows the neural pattern; the ovary, testes and, to some extent, the uterus, the genital pattern. The spleen appears to follow the lymphoid pattern, but the liver grows in closer conformity with that of the body as a whole. The heart appears to deviate from this general pattern, as does skeletal muscle. The thymus gland is an exceptionally labile organ, increasing and de-

creasing rapidly in size within short periods. It appears to follow the general pattern of growth during the first five years of life. Between five and fifteen years it changes little in size, and thereafter its weight diminishes, simulating the pattern followed by lymphoid tissue.

The subcutaneous tissue tends to increase rapidly in thickness during the first nine months after birth, while growth of the body as a whole is decelerating. Thereafter it tends to diminish, so that by five years it is approximately half as thick as at nine months. During prepubescence it again tends to increase in amount and then decreases as the growth impulse diminishes. In certain physical types the panniculus may become as thick during adolescence as it was in infancy. Girls have a greater tendency than boys to accumulate or hold fat in the subcutaneous tissues at all ages (Fig. 10). When considering nutritional status, a thickness of subcutaneous tissue which might be proper at six months would indicate obesity at six years.

The growth of muscle (Fig. 10) follows a pattern somewhat similar to that of the body as a whole, but lags behind general growth

FIG. 9. Main types of postnatal growth of the various parts and organs of the body. (After Scammon: *The Measurement of the Body in Childhood, The Measurement of Man*. University of Minnesota Press.)

BREADTHS OF SOFT TISSUES IN CALF FROM  
A-P ROENTGENOGRAMS OF LEG

FIG. 10. Breadths of muscle and of double layers of skin and subcutaneous tissue at greatest width of calf by age and sex from 3 months to 18 years of age.

The graphs reveal the close similarity in pattern of the curves for muscle to those of general growth, but a unique pattern of increase and decrease and a marked sex difference in the skin and subcutaneous tissue. (For details, see Stuart and Sobel: *J. Pediat.*, Vol. 28, and Lombard: *Child Dev.*, Vol. 21. For distribution of subcutaneous fat in childhood and adolescence, see Reynolds: *Monographs Soc. Res. Child Dev.*, Vol. 15.)

during infancy and childhood and compensates by relatively rapid growth during the late stages of adolescence. Thus it appears to combine the pattern of general growth with that of the reproductive organs during the second decade. Growth of muscle, or its potential for growth, probably extends well into the third decade and is peculiarly dependent upon activity and nutrition. The bedridden or undernourished child may increase in stature

in a fairly normal manner, but muscles will not develop normally under these circumstances.

When increase in stature ceases, the adolescent is far from physically mature. His skeletal and cardiac muscular development is particularly short of its potentialities, and he does not have the strength or endurance usually attained during the last stage of development. Although he has reached his adult height, he has not attained the customary adult breadth of shoulders and robustness. The relative proportions of bone, muscle and subcutaneous tissue are shifting during this last stage of development, even though weight and height may be changing little. Furthermore, the boy or girl may appear fully mature from the standpoint of secondary sex characters and yet not be so in the primary sex organs and therefore not in reproductive capacity.

## CHANGES IN BODY PROPORTIONS

There is a general cephalocaudal progression of growth at successive age periods. This accounts for the relatively large head and short lower extremities at birth and the progressive changes in their relationships, as shown in Figure 11. From the second half of the first year of life to puberty the extremities grow more rapidly than the trunk, and both more rapidly than the head. At puberty the rates of growth of trunk and extremities are about equal, but the trunk continues to grow after the extremities have ceased their growth in the postpubescent period.

These differences in segmental growth rates cause changes in the ratio of the sitting height to the total height. The sitting height represents about 70 per cent of total height at birth, but falls rapidly to about 57 per cent at three years. By thirteen years in girls and fifteen years in boys this ratio has fallen to its lowest point of about 52 per cent and thereafter rises 1 or 2 percentage points. As with other measurements and indices, individuals differ considerably from the average, owing to their characteristics of build and the speed of their maturation, but they tend to be consistent in this index from stage to stage of development. Since the rapid linear growth of adolescence and the fusion of epiphyses in the lower extremities occur earlier in girls than in boys, girls tend to have a lower "sitting height-total height" ratio than do boys between eight and twelve years and a higher one between fourteen and eighteen years. This ratio is useful in confirming an impression of

unusual proportions in normal children and of gross deviations in abnormal ones. For example, in a boy with arachnodactyly this ratio fell steadily from 56 per cent at three years to 47.9 per cent at thirteen years of age, then rose to 48.8 per cent at sixteen years. Corresponding average ratios for normal boys are approximately 57, 52 and 52.3 per cent respectively. These data reveal the grossly abnormal overgrowth of the extremities in this disease. In contrast, the "sitting height-

total height" ratio of children with chondrodystrophy (achondroplasia) is abnormally high. One may recognize disproportions in this respect by comparing the percentile positions held by these two measurements in relation to their respective norms, without calculating the "sitting height-total height" ratio. For example, the boy with arachnodactyly maintained a sitting height in the range of the fiftieth percentile, whereas his total height was continually above the ninety-

FIG. 11. Changes in body proportions from second fetal month to adulthood. (From Robbins et al.: *Growth*. New Haven, Yale University Press. By permission of publisher.)

FIG. 12. Development of erect posture. Lateral photographs of a boy who shows characteristic developmental changes in posture. (From unpublished studies at Harvard School of Public Health.)

seventh percentile. Norms for sitting height are given in Table 13 (p. 60).

The normal development of erect posture involves a gradual transition from the primitive, four-footed relationships of spine, pelvis and lower extremities to their well balanced weight-bearing relationships in the adult. In the former the pelvis is tilted far forward on the femurs, and an erect posture is first attained in infancy by means of a lumbar curve, somewhat compensated by a developing dorsal curve. As a result of this lumbar curve combined with undeveloped abdominal muscles, lordosis and protuberant abdomen are characteristic of late infancy and the preschool years. Only gradually does the pelvis rotate upward and the mechanically more satisfactory adult posture become established. Appropriate erect posture is usually attained during adolescence (Fig. 12).

#### VARIABILITY IN GROWTH AND DEVELOPMENT

The range of difference of most human attributes varies widely in the several age periods of childhood. The extent of the differences encountered in the United States in individuals of the same age group in such physical attributes as size, build, rate of osseous development and age of sexual maturation is probably due in part to the heterogeneity of the population. Since race has much to do

with these and other physical characteristics, homogeneous groups would not be expected to show such extreme variations.

The curve produced by plotting the measurements of most biologic material comparable in regard to age or stage of development tends to simulate the so-called normal or bell-shaped distribution curve (Figs. 13, 14). The points of clinical interest in this natural phenomenon are as follows: (1) Normal children may be expected to deviate considerably from the average in either direction. (2) The greater this deviation, the more unusual is the child in respect to his colleagues,\* and the fewer there are like him. (3) There is no point in such a distribution at which one can say that normality ends and abnormality begins, but children in the extremes of the range or outside the range deserve careful study from this point of view.

Some measurements obtained from groups of children of the same age, however, tend to produce a distorted curve when plotted in this manner; the distortion usually takes the form of a skew to either the low or the high side of the average. Figures 15 and 16 show examples of normal deviations from the cus-

\* As used in this chapter, a child's colleagues refer to other children of the same sex, age, race or other grouping which might determine the distribution curve or extent of "normality" of any given part of the body or any attribute.

FIG. 13. "Normal" distribution curve. This theoretical curve represents a type of distribution characteristic of the range of variability between values for many measurements obtained from groups of children at a given age. The percentiles indicate certain positions within this distribution, as do the standard deviations with this curve in Figures 14 and 15.

tomary bell-shaped pattern. Hemoglobin values between nine and fifteen months show a skew toward low values and a sharp upper limit beyond which they do not progress. On the other hand, weights of boys of similar height at eleven years of age produce a curve with a skew toward the high side of the aver-

age. This indicates that at eleven years fatness is more common among boys than is thinness. Distributions of a variety of physical measurements obtained from large groups of children are available as standards of comparison for all ages. Whenever any of the measurements of a child deviate markedly from those

FIG. 14. Weight at birth; rates by color and sex per 1000 live births. (After Anderson, Brown and Lyon: Causes of Prematurity. III. Influence of Race and Sex on Duration of Gestation and Weight at Birth. Am. J. Dis. Child., Vol. 65.)

FIG. 15. Distribution of hemoglobin values. The mean for the hemoglobin values is 11 gm., somewhat below that of the greatest concentration of subjects. This is due in part to the inclusion of a few infants with anemia, causing a skew to the left, and in part to a physiologic limitation to the concentration of hemoglobin, causing an abrupt end to the graph on the right. (Values from Guest, Brown and Wing: Am. J. Dis. Child., Vol. 56.)

FIG. 16. Weight distribution of 185 boys. The mean for the distribution of weights is 77.2 pounds, within the range of the column of greatest concentration of values. There is a slight skew to the right of this curve, suggesting the inclusion of a few obese subjects. (Values from Franzen: School Health Research Monograph No. II. New York, American Child Health Association, 1929.)

of his sex and age group, an attempt should be made to discover the cause or causes.

Children also differ in the rate of development or maturation. This variability has particular importance during the adolescent years (p. 147), but it is present at all ages. For example, a baby may be small and immature at birth, either because pregnancy was shortened by premature delivery or because fetal growth and development was retarded, or the span of relatively slow growth which separates the infant and adolescent cycles of rapid growth may be longer or shorter than is customary. The variations in the duration of the several stages of development are often difficult to make clinically, but the need for recognizing them is constantly arising in the appraisal of children.

The principle of variability should also be recognized as applying to many aspects of development. Distribution curves based upon age of first sitting or walking, age of appearance of specific osseous centers, age of menarche, and the like, tend to show similar characteristics. Because of such variability, all norms of growth and development should be presented and regarded as ranges rather than averages.

### OSSEOUS (SKELETAL) DEVELOPMENT

There are normal sequences of developmental changes in the many centers of ossification in

the skeleton. The specific occurrences recognized in roentgenograms and significant in relation to the child's general level of development and normality of osseous maturation are as follows:

1. The centers of the small bones and the epiphyses and processes of the long bones begin to show calcification in a characteristic sequence and at fairly predictable ages.
2. The relative sizes of centers of ossification and particularly the interrelations between them.
3. The stage of development of a bone recognized by shape, contours and processes: so-called maturity indicators.
4. The sharpness of outlines of end zones or growth lines and the densities of shadows in these areas.
5. The relations between epiphyses and diaphyses: At first the breadth of the calcium-free zone between these parts is noted, but as the time of union approaches, the degree of fusion becomes significant.

The presence or absence of certain osseous centers is most significant in infancy; shapes and contours add much information in early childhood, and the relations between epiphyses and diaphyses are particularly noteworthy during adolescence. One can usually evaluate osseous development for clinical purposes from a roentgenogram of the hand and wrist.

Girls are more advanced than boys in osseous development at all ages, as in other aspects of maturation; this difference, slight at birth, is approximately two years at puberty. Thus separate norms for boys and girls are necessary. The variability among normal children of the same sex and age is so great, however, that at any given age some boys will be more advanced than some girls. In general, children tend to be average, retarded or advanced in osseous development to much the same extent at succeeding ages.

Advance or retardation in osseous development tends to correlate well with variations in other physical attributes. For example, the osseous developments of two girls, one of whom menstruates for the first time at eleven years of age and the other at fifteen years, will tend to be similar and more nearly that of the thirteen year average than that of girls of their own ages. Retarded osseous development during adolescence is closely associated with delay in the appearance of secondary sex characters, slow growth of sex organs, late occurrence of maximal adolescent growth and, in girls, late menarche. Retardations or advances in these respects during adolescence usually do not indicate pathologic disturbances in endocrine functions, but rather normal variability in the age of occurrence of physiologic changes.

Two features of osseous development should be considered: the general stage of advance or retardation for age, and the uniformity of pattern, indicative of orderly or uninterrupted progress. General growth is affected principally by endocrine abnormalities, as, for example, general retardation in cretinism and advancement with pituitary or adrenal cortical tumors and occasionally with hyperthyroidism. Minor general retardation or advance may be related to genetic factors, but retardation is often indicative of ill health or faulty nutrition. Therefore environmental as well as intrinsic factors must be regarded as possible explanations for retarded osseous development.

The second feature of osseous development requiring evaluation has to do with irregularities in the stages of development between individual bones. Little is known about the significance of these variations, but some of the deviations in the age of appearance of individual centers are undoubtedly due to genetic factors. It also appears probable that delays in the appearance of individual centers may be caused by illnesses or other trauma at

the time when the matrix should normally be laid down.

When osseous development is grossly retarded, it is customary to assign a skeletal (osseous) age to the child which may be compared with chronologic age, mental age and expressions of abnormality in other aspects of development. Various methods of appraising skeletal age have been developed, the *Atlas of the Hand* by Greulich and Pyle now being in wide clinical use as a standard of reference. An *Atlas of the Knee* by Pyle and Hoerr is also available. None of these can be used effectively without study and experience.

#### DENTAL DEVELOPMENT

The primary and secondary teeth erupt in characteristic sequences and at ages predictable within rather wide ranges of variability. Advance or retardation in the *timing* of eruption of teeth shows definite consistency. If the first tooth erupts early, subsequent teeth will usually do so throughout both dentitions. Age at the time of eruption appears to have a strong genetic predetermination. Eruption of teeth may be greatly delayed, however, by nutritional disturbances and by other conditions which inhibit growth in general. Retardation in the growth of the jaws may also interfere with the sequence of eruption as well as with the alignment of the erupted teeth.

The calcification of the teeth also proceeds according to a characteristic time schedule and sequence, starting about the fifth fetal month in the first primary teeth and continuing until the last permanent tooth is fully calcified in early adult life.

The quality or structure of the teeth, and hence their resistance to decay or other acquired defects, in some measure depends upon genetic factors, but internal and external environmental factors unquestionably play an important part. For example, maternal health and diet may exert considerable influence upon the fetal calcification of the primary teeth. Dental defects originating in utero are usually not recognized until the teeth have erupted. So, also, nutritional disturbances in infancy, particularly celiac disease, may scar permanent teeth being formed at the time, and these scars are not observed until after eruption during the school-age period. Although it is impossible to assign a specific cause to many of the dental defects, there is evidence that lack of vitamins A and D, of calcium and of ascorbic acid interferes with normal tooth development in fairly character-

Table 5. Age Periods of Life before Maturity

NAME OF PERIOD (SYNONYMS)	AGES REPRESENTED (APPROXIMATE)	EXAMPLES OF FEATURES CHARACTERIZING
Embryonic.....	1st trimester of prenatal life	Rapid differentiation Establishment of systems and organs
Early fetal.....	2nd trimester of prenatal life	Accelerating growth Elaboration of structures Early functional activities
Late fetal.....	3rd trimester of prenatal life	Rapid increase in body mass Completion of preparation for postnatal existence
Parturient.....	Period of labor and delivery	Risk of trauma and anoxia Discontinuance of placental circulation
Neonatal (Early infant; new-born).....	1st month of postnatal life	Initiation of respiration and other functions Postnatal adjustments in circulation
Infant proper (Middle infant).....	1 month to 1 year	Rapid growth and maturation Increase in functions, especially of nervous system
Transition (Late infant).....	1 to 2 years	Decelerating growth Progress in walking and other voluntary motor activities and in control of excretory functions
Preschool (Early childhood; run-about child).....	2 to 6 years	Slow growth Increased physical activity Further coordination of functions and motor mechanisms Rapid learning
School (Midchildhood).....	Girls: 6 to 10 years Boys: 6 to 12 years	Steady growth Developing skills and intellectual processes
Prepubescent (Late school or early adolescent).....	Girls: 10 to 12 years Boys: 12 to 14 years	Accelerating growth—rapid gain in weight Early adolescent endocrine and sex organ changes
Pubescent (Adolescent proper)....	Girls: 12 to 14 years Boys: 14 to 16 years	Secondary sex character maturation Maximum growth increase
Postpubescent (Late adolescent or youth).....	Girls: 14 to 18 years Boys: 16 to 20 years	Decelerating, terminal growth Rapid muscle growth and increased skills Rapid growth and maturing functions of sex organs Need for self-reliance and independence

Reproduced from Stuart: Introduction to Pediatrics; in Brennemann: Practice of Pediatrics. W. F. Prior Co. Vol. 1, Chap. 2.

istic ways. The fluoride content of drinking water habitually taken during the growth period has an important relation to the structure of the teeth, and oral hygiene is an important factor in protecting developing teeth from caries. The calcification of the teeth may be regarded as a permanent health record; teeth commonly show manifestations of past disease by changes in morphology and color.

Table 4 gives the chronology of human dentition from the standpoints of calcification and eruption, and, for the primary teeth, of their shedding (see also p. 623). The wide variability in age at the time of these occurrences is correlated only to a limited degree with general advance or retardation in growth and development; it appears to be in large measure an independent attribute. The sex differences are not presented separately, because the variability is not great, though, on the average, girls are slightly advanced over boys.

### AGE PERIODS OF LIFE BEFORE MATURITY

The years before maturity may be divided into periods characterized by certain features of growth and development. Although these divisions are not sharply delimited and are somewhat artificial, they form a convenient pattern within which to discuss growth and development. Table 5 lists these periods and indicates the principal features of each.

#### PRENATAL PERIOD

Study of growth and development should begin with conception, because the child has passed through the most rapid and hazardous changes associated with these processes by the time of birth, or at least within a few days after it. The incident of birth is important because of the physiologic changes required for extrauterine existence.

In the first trimester, or *embryonic period*, organogenesis proceeds rapidly and is almost complete by the end of the third month. During the first few weeks the future fetus is a self-contained organism deriving its nutrition largely from its own yolk granules. Damage to the embryo or abortion during this period is likely to be due to mechanical faults of implantation or to embryonic defects. During the remainder of the first trimester maternal disease and malnutrition may exert their most damaging effects. Each body part arises at a definite moment in a rigid sequence of fetal development. If the embryo is damaged—by rubella, for instance—organs or

organ systems forming at the time may be malformed or completely arrested. Unfortunately, many women are not aware of the hazards of disease and malnutrition peculiar to this phase.

The second trimester of pregnancy, or *early fetal period*, is a safer time for the developing organism. By the beginning of this period the fetus is a fairly complete human being with its organs differentiated and is largely beyond the danger of malformation. Implantation is secure; dangers of infection and abortion are slight. Maximum growth in length occurs during this period (Fig. 7), and by the end of the period the fetus has attained 70 per cent of the length it is to be at birth. It has laid down almost no subcutaneous fat, however, and has achieved only 20 per cent of its birth weight.

In the last trimester, or *late fetal period*, the developing organism is again beset by the hazards of infection and of abortion. Syphilis may be acquired at this time, and a luetic mother should start antisyphilitic treatment well before this trimester begins. This trimester is characterized by increasingly rapid gains in weight. Thus the fetus, which weighed approximately 700 gm. at the end of the second trimester, is gaining at a rate of over 200 gm. a week by the middle of the third trimester, to achieve a birth weight of about 3500 gm. Since mortality rates of premature infants correlate directly with their birth weights, every week that a mother continues to carry her infant toward term increases his chances of survival.

Fetal growth follows the cephalocaudal law, and the central nervous system grows rapidly, constituting 25 per cent of the body weight by the end of the second month of pregnancy. The possibilities of damage to this rapidly growing organ early in pregnancy are obvious. Even at term the central nervous system accounts for 15 per cent of the body weight, and premature infants have relatively large heads.

#### PARTURIENT PERIOD

At the end of approximately the tenth lunar month in utero the infant must pass through one of the most dangerous experiences as he traverses the birth canal. However, his body has certain attributes which help to protect him from the trauma of birth. He is well padded with subcutaneous fat to protect his internal organs and shield him from the shock of a cold, extrauterine world. He is limp, and

his joints are pliable; he folds with facility into a position mechanically advantageous for delivery. The sutures of his skull are patent, and the component bones can override to some extent with safety to allow easier birth of the head. His skeleton is still somewhat flexible, and pressure on his bones tends to bend rather than fracture them. Perhaps most important of all, his brain is much less sensitive to oxygen lack than is that of an adult.

Unfortunately, certain physical characteristics of the newborn make him vulnerable to birth trauma: The skull bones may override to such an extent as to damage his brain; the resultant shock is mildly evident in most infants by their drowsy, dazed behavior in the first hours of life, and is tragically evident in some in their limp musculature, subnormal temperature and difficulty in initiating extrauterine respiratory movements. Indirect evidence of the fragility of blood vessels in the newborn, and the ease with which intracranial vessels are torn, is found in the fact that in about 50 per cent of all neonates the cerebrospinal fluid reveals evidence of fresh hemorrhage.

The fetus makes respiratory movements prenatally; when he leaves the uterus, these movements normally become stronger and deeper. The first effective gasp must expand the lung, stretching its elastic fibrils and separating the cohesive, cuboidal cells of the alveoli. The lung is collapsed at birth and has none of the potential of the adult lung to spring back to a semiexpanded position when applied external pressure is released; hence most attempts at artificial respiration fail. The infant who does not begin to breathe spontaneously frequently has damage of his central nervous system and is in shock.

The liver of the newborn infant may extend 2 or more cm. below the protective thoracic cage and is vulnerable to injury, especially if rough tactics of artificial respiration are used. The adrenal glands, which have highly vascularized androgenic zones at this stage, are easily damaged, particularly in a breech delivery; such damage is usually lethal. The limp neck muscles may allow the cervical or brachial plexuses to be stretched and torn, or the vertebrae to be dislocated, by an overzealous operator.

The clavicles are the first bones to calcify in utero; fractures of the clavicle occur more frequently during birth than all other fractures combined.

Immediately after birth the umbilical cord

can deliver approximately 100 additional ml. of blood to the baby as the contracting uterus squeezes it out of the placenta.

The firstborn infant tends to be lighter in birth weight than subsequent siblings. This may be important to bear in mind when a mother has difficulty because of cephalopelvic disproportion with her first infant: Her second infant may not be deliverable by the pelvic route. In general, white infants are heavier than Negro infants at birth. Figure 14 (p. 19) shows the range of birth weights usually encountered in this country. There are considerable differences in the weights for other countries. Birth weight is a significant index of the state of development of the organ system of the body and therefore is valuable as an index of viability. It also reflects differences in maternal nutrition and socio-economic status.

In this country a birth weight of less than 2500 gm. ( $5\frac{1}{2}$  pounds) is used as the statistical criterion of prematurity. However, it will be seen from the foregoing that a Negro infant of 2000 gm. might be less immature than a white infant of the same weight. Data concerning premature births must be analyzed with further caution when they are obtained from countries where varying indices of prematurity are used, such as body length, foot length or a birth weight of less than 2272 gm. (5 pounds).

#### NEONATAL PERIOD

During this period, usually defined as the first month of life, although its main characteristics relate principally to the first two weeks, the neonate must make profound adjustments to his new environment. About 72 per cent of all infant mortality occurs in the first month of life, and half of this occurs in the first twenty-four hours.\*

In the first three or four days of life the infant loses weight. He may lose up to 10 per cent of his birth weight without causing concern; small infants lose proportionately less than large ones. This weight reduction largely represents loss of excess body fluid, and it is illogical to try to prevent it by forced feedings. Usually, by the fifth day, the infant begins to gain; many infants regain their birth weight by the tenth day, and most by the fourteenth.

\* Infant mortality is expressed as a rate which states the number of deaths under one year of age for every 1000 live births, and neonatal mortality is a similar rate for the first month of life.

Generous bottle feedings in the first few days of life result in a more rapid gain, and, though the breast-fed infant will usually gain more slowly, this slow gain is not an indication for adding cow's milk feedings to his diet.

The newborn infant has a strong hunger drive and will "root" about with his lips and tongue for milk. His sucking reflex is present at birth; his strong masseter muscles and his fat-padded cheeks (the "sucking pads") help to make this reflex mechanically effective. But the strength of his sucking depends directly upon the degree of his hunger, so that it is not wise to feed the infant water or sugar solution in his first two or three days if it is desired that he stimulate his mother's milk flow by strong sucking. Rarely the infant becomes dehydrated during these first few days before his mother's milk appears in adequate quantity. A decided loss in weight about the third day, associated with fever, is presumptive evidence of dehydration and is an indication for additional fluid intake.

The normal newborn is tense and lies with arms, legs and fingers flexed. The most accurate method for measuring the infant's length is to flatten him out on a smooth, straight, graduated board equipped with one fixed and one sliding upright.

The skin of the newborn is covered with greasy vernix caseosa. About the end of the first week of life the fine hair called lanugo, which may cover large areas of the body at birth, will have been shed. For the next two weeks the epidermis tends to flake off, especially if the vernix has been left in place; the mother must be told that this desquamation is normal and temporary.

The neonate frequently has small, capillary clusters or nonelevated hemangiomas on the nape of his neck, over the bridge of his nose or on his eyelids. These usually disappear before he is a year old and never require treatment.

Because of overriding of the skull bones the circumference of the skull and the size of the anterior fontanel may be smaller in the first few days of life than they would be otherwise.

The scalp may be covered with thick black hair extending well down over the forehead. Neither this hair, which will largely be shed and replaced by permanent hair, nor an absence of hair has any prognostic value as to future color, amount or texture.

The face of the newborn is round; the

mandible is less well developed than the maxilla, appears to recede, and is frequently asymmetrical in the first few weeks of life as a result of intrauterine pressures; the forehead is high and may appear to bulge. Small ethmoid, maxillary and sphenoid sinuses are present at birth and appear cloudy and opaque on roentgenograms because of redundant mucous membrane linings. Although the sinuses can become infected, they do not have great clinical significance at this time. The short, relatively wide eustachian tube, which enters directly into the pharynx, may easily convey infection to the middle ear and mastoid antrum, which are well developed at birth. The resulting otitis media may be masked by the fact that the tympanic membranes are still thickened by an internal layer of connective tissue which hides signs of infection and allows the ear drum to bulge only under considerable pressure. The mucoid material which fills the middle ear cavities and mastoid antrums in the first few days must not be mistaken for inflammatory exudate if the ear drum is incised.

The eyes of the newborn cannot focus. Extraocular movements are not usually coordinated in this period and may not be for several months. The sclera is distinctly bluish, the iris is usually unpigmented and gray-blue, and the optic disk has a peculiar grayish hue. Although the neonate reacts to bright light and to gross objects passed before the eyes, he has little true vision.

The lacrimal glands do not secrete tears until several weeks after birth. At the time secretion first appears the lacrimal ducts may not yet be open, and tearing may be noted. This is not an indication for attempts to open the ducts mechanically, since the condition is usually self-limited.

The frenum of the tongue of the newborn is normally short and tight. This does not mean that the baby is "tongue-tied" and is not an indication for slitting the frenum. The action of the tongue is not important in nursing, and the wise physician will not implicate "tonguetie" as a cause of ineffective feeding.

The chest is nearly circular, and the heart tends to assume a horizontal position, which places the apex beat at about or outside the left nipple line and in the fourth interspace. The lungs may require several days to achieve full expansion, especially at their bases, and basal rales heard during this period are not necessarily cause for concern.

The abdomen is protuberant because of

weak rectus muscles, large internal abdominal organs and sometimes considerable subcutaneous fat. A separation of the sheaths of the rectus muscle along the midline of the abdomen, *diastasis recti*, is not unusual and requires no treatment.

Normally, the umbilical cord mummifies and sloughs off cleanly at the junction of the cord membrane and the skin on the sixth to the tenth day. The blood vessels close functionally at birth, but do not obliterate with fibrous tissue until about the end of the third week. The thrombi which seal them during this period form dangerous potential channels for infection, and the umbilical stump requires special cleanliness for a week or more after the cord has dropped off. Umbilical hernias are common in the newborn, but must not be confused with the occasional umbilical puckering which involves only abdominal skin. These hernias should not be strapped in the neonatal period, because of the danger of infection.

The prepuce is always adherent to the glans and does not separate for several months. The practice of stripping it back at birth is to be condemned. If there is an opening in the prepuce sufficient to permit unobstructed urination, circumcision is not mandatory.

The legs are bowed. With the thighs flexed, the knees can easily be abducted until the legs reach nearly a 90-degree angle with the perpendicular. It is important to attempt this maneuver with all newborn infants and to repeat it in examinations throughout the first two months; failure of easy abduction is indicative of muscle spasm about the hip and is the earliest presumptive sign of a potential dislocation of the hip.

The complex changes in circulation which occur when the cord is cut are described on page 840, but these dramatic anatomic adaptations are not completed immediately. Normal femoral pulsations may not be palpable, and heart murmurs may be discernible for several weeks and may signify merely leakage of blood through fetal channels which have not yet been obliterated. "Cyanotic types" of congenital heart disease may not cause cyanosis in the early weeks of life. Therefore a diagnosis of congenital heart disease in the newborn infant should be made with great caution.

The thymus, which continues to grow rapidly until five years of age, when it has trebled its birth weight, is normally large at

birth and is revealed roentgenographically, especially in the expiratory phase of respiration, as a prominent shadow at the base of the heart. The thymus has never been directly implicated as a cause of respiratory difficulty, and radiation therapy of it, with its possible hazards, has become a rare procedure.

The newborn usually urinates soon after birth, but this event may be delayed for one or two days without causing undue concern. The early voidings contain uric acid crystals which may stain the diaper pink; such staining must not be confused with bleeding.

The infant has his first bowel movement soon after birth; the stools (meconium) are sticky, greenish-black and without odor. When he begins to ingest milk, these meconium stools change gradually to normal stools, usually at the end of the first week.

Within a few days after birth, owing largely to hormones absorbed from the mother, neonates of either sex may exhibit swollen, tense breasts from which milk ("witch's milk") may ooze. This is a physiologic reaction, and no harm comes of it unless attempts are made to squeeze out the milk; such a maneuver may cause formation of a breast abscess.

A few days postnatally there may be a mucoid or mucosanguineous vaginal discharge which is also the result of maternal hormones and is to be considered normal.

The newborn can usually raise his head while lying prone. There is little danger that the healthy infant will smother when allowed to lie on his abdomen, and many supposed instances of smothering have proved on post-mortem examination to be cases of overwhelming infection. Nevertheless it is prudent to use no pillow, to provide a firm mattress and to avoid constricting garments.

The peripheral circulation of the newborn often is not sufficient to keep his extremities as warm as the rest of his body, nor is this necessary. The mother should be reassured on this point, or she will keep her infant overwarm. She should also be told that the skin of the normal newborn usually takes on a mottled, purplish hue when exposed to air.

#### PERIOD OF INFANCY

During the period of infancy, the first two years of life, growth continues at a rapid, though generally decelerating, rate.

Gain in weight during the first three months of life averages approximately 1 ounce per day. However, these large increments

lessen steadily: by the age of five months the infant has usually doubled his birth weight, by the age of one year he has only tripled it, and he will be two and a half years of age before he quadruples it. His mother must be forewarned that the daily gain of 1 ounce which he accomplished in early infancy will not continue and that his appetite will be relatively less as his rate of growth slackens; otherwise she will worry over what she thinks is unsatisfactory progress and urge unwanted food upon him. It is in this way that many feeding problems arise.

Subcutaneous fat increases in amount until the age of about nine months, accounting for the traditionally chubby appearance of infancy, but diminishes thereafter (Fig. 10, p. 16). In the healthy infant this fat feels firm and is a valuable indicator of the state of his nutrition. This chubbiness must not be mistaken as an indication for putting him on a reducing diet. Nor must the normal loss of subcutaneous fat after this age period, when he is being transformed into a lithe, active child, be cause for worry about possible malnutrition.

Growth in length shows a similar progressive slowing up: The infant's birth average of 50.6 cm. (20 inches) is increased by 20 per cent at the age of three months, by only 50 per cent at one year, and by only 75 per cent at two years. He will not double his birth length until he is almost four years of age.

Head circumference increases considerably during the first year of life, owing to extremely rapid growth of the brain. The brain averages 350 gm. at birth and weighs two and a half times as much by one year of age, but less than four times its birth weight at full maturity. The circumference of the head should be recorded at intervals throughout infancy. Such information may provide the clue for early detection of significant intracranial disturbances. When increase in size is too slow, one should suspect failure of adequate brain growth resulting in microcephaly or of premature closure of the sutures (stenocephaly). When increase in size is too rapid, hydrocephalus may be developing, or there may be a space-taking lesion such as a subdural hematoma. The usual head circumference at birth of 35 cm. (13.8 inches) increases by 17 per cent at three months, but only by 25 per cent at six months, and 33 per cent at one year. At the age of six years head circumference has increased only

50 per cent over the birth measurement and has almost achieved adult size.

The circumferences of the head and chest are nearly equal during the first year in the average infant. Striking inequality in these measurements suggests an abnormality, either of the head or of the chest. Stem length corresponds closely in value to these two circumferences during the early months of the first year (Table 6), but thereafter becomes progressively greater.

Small defects in skull ossification which border suture lines are not unusual and are not to be construed as evidence of rickets.

The infant's skull has six fontanels, but only two are found on physical examination. The posterior fontanel has little clinical significance and may not be evident. The anterior, or bregmatic, fontanel, however, merits careful examination during infancy. It is at the junction of the frontal and parietal bones and averages about 2.5 cm. in diameter in the first weeks of life after molding of the skull from birth pressures has disappeared. It may increase in size during the first two or three months, but then normally becomes smaller and is obliterated between eight and fifteen months. A small anterior fontanel is suggestive of microcephaly; delay in closing is suggestive of rickets, cretinism or hydrocephalus.

The rapidity of growth during infancy probably accounts for the relatively large requirements for vitamins A and D and ascorbic

Table 6. Median Values for Circumference of Head and of Thorax and for Stem Length by Age in the First 5 Years of Life

Age		Head Cir- cumference		Chest Cir- cumference		Stem Length	
Yr.	Mo.	In.	Cm.	In.	Cm.	In.	Cm.
	Birth	13.8	35.0	13.0	33.0	—	—
	3	15.9	40.4	15.8	40.2	16.0	40.7
	6	17.1	43.4	17.1	43.4	17.6	44.6
	9	17.8	45.3	18.0	45.7	18.5	47.0
1	— 0	18.3	46.6	18.6	47.3	19.2	48.8

2	— 0	19.3	48.9	19.8	50.4	21.3	54.9
2	— 6	19.5	49.5	20.2	51.4	22.0	56.0
3	— 0	19.6	49.8	20.6	52.2	22.6	57.5
3	— 6	—	—	20.8	52.8	23.2	59.0
4	— 0	19.8	50.4	21.0	53.4	23.9	60.6
5	— 0	20.0	50.8	21.5	54.6	24.8	62.9

From studies at Harvard School of Public Health. For percentile distributions of these measurements by sex, see Tables 11 and 13 (pp. 56, 60).

acid; these must be given early and in adequate amounts if rapidly growing epithelium, mesenchymal tissues and bone are to develop properly. The infant requires large amounts of water daily (about 75 cc. per pound of body weight), since his basal rate of heat production per pound is twice the adult rate because of his relatively larger surface area. As the rate of growth slackens, the need of about 55 to 60 calories per pound of body weight in the early months decreases to about 45 calories at the end of his first year.

The feeding reflexes of the infant are not sufficiently mature to propel a bolus of food from lips to pharynx, where the swallowing reflex takes hold. Hence soft and semisolid foods should be introduced well into his mouth. The infant must be fed with patience in this early period, with the knowledge that he may unwittingly spit out much of what is fed to him.

Deciduous teeth are far advanced in development at birth (p. 25). The first teeth to erupt are usually the mandibular central incisors at about six months of age, but they may be delayed until the end of the first year. There are twenty deciduous teeth, of which all but the four second molars usually erupt between six and eighteen months of age. This is a period during which respiratory and other febrile illnesses are common; teething may occasionally be painful and is frequently accompanied by redness and swelling of the gums, but fever and convulsions can rarely, if ever, be attributed to this process. Most of the permanent teeth begin calcification during infancy; nutritional disturbances and infectious diseases at this time may cause defects which are not recognized until the teeth have erupted.

Vision seems adequate even in the young infant, though absence of cones from the retina during the first few months of life suggests that colors cannot be distinguished. The small eyeballs create a physiologic hyperopia which is slowly corrected in childhood as they grow relatively more in their anteroposterior dimensions. Extraocular movements should begin to coordinate after the first few months of life.

The infantile larynx is small, and minor infections with resultant edema easily impede the airway. After the period of infancy it grows rapidly, and babies who suffer from recurrent croup usually become free of this hazard after the age of two to four years.

The nasal passages in infancy are tiny, and minute amounts of secretion block them; it is fortunate that even the young infant can sneeze vigorously. Mothers must be reassured that sneezing is common and usually is not a sign of respiratory infection. The eustachian tubes remain widely patent and offer infection easy access to the middle ear cavities and the mastoid antrum.

After one month of age the sweat glands become more active. The overclothed infant may then be better able to control his body temperature, but he runs the risk of skin irritation from the resultant perspiration.

The infant differentiates between sweet and sour; oversweet feeding mixtures may create difficulties when unsweetened foods are introduced. His palate is keenly aware of temperature changes, and an artificial feeding mixture must be given at a temperature to which he has become accustomed; its temperature is not important, except that it be not unduly hot. There is no harm in giving an infant cold milk if he will accept it.

The infant's bladder has a powerful detrusor muscle, but sphincter control is weak and not yet under the influence of the cerebral cortex. It is futile to attempt bladder training before conscious inhibition of bladder emptying is anatomically feasible. This does not usually occur before the end of the first year, and the child may be two and a half or three years of age before bladder control is reliable. Bowel control, however, may begin as early as the eighth month.

Several typical reflex responses, resembling those of a decorticate animal, may be elicited. They are of clinical interest because their continued presence in the older child is abnormal. Stimulation of the lateral edge of the infant's foot elicits a *plantar* reflex, which may result in extension of the toes; the normal response of flexion should become established between the first and second years. Persistence of the infantile reaction after this time suggests a pyramidal lesion. Stimulation of the ball of the foot elicits a *grasping* reflex which persists until the age of standing. The *abdominal* reflexes may be elicited in about one third of newborn infants as a diffuse contraction of the abdominal muscles which may also involve the extremities; mature quadrantal responses should develop between six and twelve months. The *sucking* reflex, activated by stimulation of the lips or cheeks, is present at birth; its persistence after the first year may be considered abnormal. The *grasping*

reflex, by which the infant flexes his fingers and hands tightly around objects placed in them, resembles the forced grasping of an older person with a lesion of the frontal lobe; it should disappear between the second and fourth months. The *Moro* reflex, which consists in a symmetrical and consecutive outward, upward and inward grasping motion of the arms, is elicited by startling the infant, as by slapping his mattress sharply. A lack of symmetry of the movements suggests a brachial palsy or a fractured clavicle on the immobile side; the reflex may be absent in the presence of diffuse cerebral birth injury. This reflex should disappear between the third and fifth months. The *tonic neck* reflexes, which result in extension of the arm and occasionally of the leg on the side to which the head is turned and a flexion of the contralateral extremities, should disappear about the middle of the first year. The *otolith* righting reflex may not be present at birth, but should appear by the end of the second month and remain throughout life. It is elicited by covering the infant's eyes, holding him at arms' length in a symmetrical grasp and tilting him forward, backward and laterally; the reflex will cause his head to rotate in a direction which tends to keep it upright.

The sacrococcygeal curve of the spine is present at birth, but the remainder of the spine either forms one long continuation of this curve or is straight. Almost from birth the infant can raise his head from the mattress while lying prone, and the cervical curve develops as he begins to hold his head erect. By the third or fourth month he may be expected to sit with support, and by the seventh to sit alone. By the time the infant is eight or nine months of age he can usually stand with support, and at some time between the tenth and fourteenth months he can stand alone. Standing is first accompanied by a sharp lumbosacral angulation, since the pelvis remains tilted forward in the infantile position for some time. The infant may begin to creep at about nine or ten months, but some infants never manifest this transitory stage of motor development. Shortly after standing with support, the infant will walk if led and will usually walk alone at some time between the tenth and fifteenth months. The true lumbar curve and compensating dorsal curve gradually develop with walking.

By the time he begins to walk the infant has usually lost the bowlegs characteristic of

earlier infancy. Throughout most of his second year he walks clumsily on a wide base, with his legs apart and his feet out-toeing for better balance. His feet are pronated and appear flat, because relaxed ligaments allow the arches to sag, and fat pads fill their concavities. New shoes should be long enough to allow at least  $\frac{1}{2}$  inch beyond the limit of the big toe, because foot growth is rapid in this period. Proper shoes have straight medial borders, flat soles and firm heel structures against which the child may brace his feet in walking. Shoes should be discarded before they become so inadequate in length as to retard foot growth.

It was noted earlier that growth is relatively easy to measure, but that development, involving an increase in complexity of structure and function, is more difficult to evaluate. Table 7 presents certain norms for use in the general appraisal of infant development. Definite deviations from the progress indicated by this table call for study of the infant by a trained examiner. The accomplishments given for the different ages represent average ones; the actual range of normal achievement is broad.

#### PRESCHOOL PERIOD

The preschool years, ages two to six, encompass a period of relatively slow growth. With an average yearly gain in weight of less than 5 pounds, the child who tripled his birth weight in the first year of life manages only to double this one-year weight by his sixth birthday. He does little better than double his birth length during his first six years, but, growing relatively more in height than in weight, he appears to be tall and thin. By the end of this preschool period his head circumference has almost attained adult size.

The rapid changes of fetal and infant life have largely been completed, and the child is learning to coordinate motor mechanisms and functions which have been developing up to this time. He has learned to walk and to talk. He is incurably interested in the world about him and explores it with physical activity and questions which may tax the patience of his elders. This is his way of learning and developing, and it must be tolerated wisely.

Dental care is extremely important in this age group. The deciduous teeth number twelve less than the permanent teeth, but they fill the entire jaws until these structures begin to enlarge at about four years, in anticipation

**Table 7. Principal Motor, Social, Play and Speech Manifestations  
by Months of Age during First 2 Years\***

*One Month*

Generalized reaction to stimulation; mass activity; can hold chin up when prone; focuses eyes on object and watches person; cries from discomfort.

*Two Months*

Can raise chest when prone; eyes follow moving object; averts head from light; smiles at person and listens to voice; coos.

*Three Months*

Supports head steadily; reaches and misses; waves at toy; makes defense movements or selective reflex withdrawal reactions; listens to music; prefers mother; says "aah, ngah."

*Four Months*

Pushes with feet when held erect; sits with support; reaches for rattle; touches adult's hand; puts hand to mouth; plays with own hand; laughs aloud.

*Six Months*

Sits propped; squirms when prone; grasps and holds moving toy; puts toy in mouth; knows stranger; enjoys mirror; babbles to person.

*Eight Months*

Rolls over; sits alone; stands with help; pats toy; transfers it from one hand to other and puts it in mouth; discovers that toy falls down; plays with toes; stretches arms to come; calls for attention; pulls hair; practices consonants.

*Ten Months*

Stands if held; creeps; hitches; picks up pellet; points index finger; exploits adults; plays "peek-a-boo" and waves "bye-bye"; scolds; expresses joy; uses a word meaningfully; knows names frequently heard as own, siblings' or pets'; lifts on to hands and toes.

*Twelve Months*

Walks if led; pulls to stand and "cruises" by holding to furniture; exploits toys; notices babies; repeats words; recognizes sound and obeys "no, no"; plays "pat-a-cake"; draws adults into play.

*Fifteen Months*

Stands and walks alone; climbs stair steps; opens boxes; pokes fingers into holes; marks with pencil; names objects and familiar pictures; responds to familiar phrases.

*Eighteen Months*

Runs; puts block in hole; explores drawers and furniture; seeks help when in trouble; uses adjective-noun phrases.

*Twenty-one Months*

Climbs on furniture; jumps; explores further; obeys simple commands; uses verbs and pronouns.

\* Adapted from Mary Shirley, Harvard School of Public Health.

The sequence of appearance of these behavior manifestations is characteristic, but the age of accomplishment of each differs considerably within normal limits among individual infants. The reactions listed at each age are those customarily becoming manifest during the preceding interval. In using the table one must avoid the conclusion or even the implication that a child whose development is behind the schedule is necessarily retarded.

*Table 8. Illustrations of Average Development of Neuromotor and Mental Abilities from 2 to 9 Years\**

*Two Years*

Names familiar animals and objects such as dogs, cats, key, penny, watch; tells experiences; plays catch and toss with a ball; can run; can walk upstairs by holding onto railing; uses simple sentences and phrases; builds a tower of 3 or more blocks; can be taught to put away toys in proper place; folds paper once, imitatively; listens to stories illustrated with pictures; asks for things at table by name; helps to undress himself; can open doors; uses toilet during waking hours.

*Three Years*

Can tell whether a little boy or a little girl; repeats 3 numbers; enumerates objects in a picture; knows his own family name; repeats a sentence of 6 syllables, e.g., "It is cold and snowing"; may try to sing; jumps, tries to dance; can walk backwards; can go downstairs alone; can ride tricycle; attempts to draw pictures and to string beads; can copy a circle; plays simple games; can help dress himself; can unbutton clothes; can wash hands, and perhaps brush teeth; does not wet bed.

*Four Years*

Names 3 familiar objects in succession, e. g., key, knife, penny; repeats 4 numbers; uses scissors in cutting out pictures; points out longer of 2 lines; climbs well; plays games with several children; can count 4 pennies; can copy a square.

*Five Years*

Tells which is the heavier of 2 weights; repeats a sentence of 10 syllables, e.g., "His name is John, he is a very good boy"; reconstructs oblong card which has been cut diagonally into 2 pieces; names 4 colors, e.g., red, blue, green, yellow.

*Six Years*

Counts 13 pennies; knows whether it is morning or afternoon; defines common objects, e.g., fork, chair, table, in terms of what they are used for; obeys triple commands in succession, e.g., puts key on chair, brings box, shuts door; shows right hand and left ear; says which is pretty and which is ugly of a series of drawings of faces; describes the objects in a picture, not simply enumerates them.

*Seven Years*

Notices that certain parts are missing from drawings of incomplete figures; can copy a diamond; repeats 5 numbers in succession, e.g., "4, 7, 3, 9, 5"; can repeat 3 such numbers backwards.

*Eight Years*

Gives similarities and differences between 2 things from memory, such as fly and butterfly, wood and glass, paper and cloth; counts backwards from 20 to 1; repeats the days of the week.

*Nine Years*

Describes common objects in detail, not merely their use; knows the date; repeats the months in order; tells time; makes change out of a quarter, arranges 5 weights in order of heaviness; can repeat 4 numbers backward.

\* Adapted from data by A. L. Gesell, by J. S. Plant.

of the more numerous permanent teeth. Caries of the deciduous teeth nearly always begins during the preschool years and may spread rapidly. The deciduous teeth act as guides for the positions of the permanent teeth, the deciduous second molars being especially important in this respect. The permanent six-year molars, which erupt behind them, tend to drift anteriorly under normal circumstances. This drift is exaggerated when a deciduous second molar is lost prematurely; as a result, the permanent canine teeth, which erupt late, may be crowded out of line.

The preschool child should gradually overcome his infantile lordosis, learn to walk with a narrow base, and lose the waddle of infancy. Foot pronation should correct itself, and foot arches should begin to develop. The child may be expected to make great progress from an infantile toward an adult posture and gait. This is a period of relative thinness, loose ligaments and limited musculature, and constant physical activity during waking hours; hence chronic fatigue and functionally poor posture are common.

Table 8 presents illustrations of the average neuromotor development and mental abilities from two through nine years of age.

The lively interest of the preschool child in exploring his environment and many other matters causes him to have much less interest than formerly in eating. This must be dealt with by other means than attempts to force him to take unwanted food. Diet regulation, immunizing procedures, gastrointestinal and dermatologic difficulties are not the important items they were in infancy. Respiratory infections are common, but seldom serious, yet collectively they provide a considerable block of the medical problems of this age. The non-preventable contagious diseases are relatively frequent, but serious complications have been greatly reduced.

Accidents are the leading cause of death in childhood, killing more than 17,000 children each year in the United States. About half of the deaths occur in those under five years. During this time the physician can help parents teach their children the importance of accident prevention (p. 143).

Most frequently the preschool child and his mother need the physician's help and guidance in smoothing over the problems which arise when an easily controlled infant begins to exhibit a more mature personality and a stronger ego not yet controlled or socialized. His needs for independent, yet super-

vised, opportunities to explore his environment as well as for love and protection are greatly increased, and his attempts to fulfill these needs mean constant impacts against the family and home environment. The mother must be shown how to cope with these activities and needs in a common-sense, practical way so that the child is not completely frustrated, but explores his environment with safety to himself and a minimum of chaos to the family. Routine visits to the physician's office may often consist principally in interpretative and reassuring talks with the mother.

#### SCHOOL PERIOD

The so-called school period, six to ten years in girls, and six to twelve years in boys, is characterized by increasingly slow growth in height and increasingly rapid gain in weight, so that the child tends to lose the thin, wiry appearance of his preschool days. Growth in general is slow and will not deviate from this pattern until the onset of puberty, which is marked by an accelerated gain in height and a still more accelerated gain in weight.

In the school period the child is frequently exposed to the common communicable diseases. It is wise to follow his growth carefully during this time, since it may be affected adversely by malnutrition resulting from repeated infections or faulty habits of diet. The child may have insufficient time for breakfast, he may have a scanty lunch, and may show a general lack of interest in his diet, which is often poorly supervised. Some children, however, become progressively more obese during these years. This trend should be recognized promptly and its emotional as well as dietary causes sought.

Vision must be tested at least annually; refractive changes commonly result from growth in the anteroposterior diameter of the eyeball, and myopia may develop rapidly. As a result of middle ear infections or blockage of the eustachian tubes by lymphatic tissue, deafness is not uncommon. Hearing acuity should be tested at least every two years, or whenever progress in school becomes unsatisfactory.

Lymphatic tissue reaches the height of its development in this age period, and large adenoids and tonsils are physiologic. Size alone is not an indication for their surgical removal unless they are foci of infection or cause serious mechanical obstruction.

The vertebral bones and ligaments are still

relatively malleable. Long hours in an ill-fitting chair before an inappropriately sized desk and other undesirable postural habits result in functional, and ultimately may lead to permanent, structural curvatures of the spine. The child of this age should have overcome his earlier lordosis, but if he has not done so or if functionally abnormal curvatures have developed, an effort should be made to develop better muscles and postural reflexes. Persistently poor posture is suggestive of chronic fatigue and malnutrition.

The bones of the face grow rapidly after late infancy. The frontal sinuses are fairly well developed by about six years of age, and all the sinuses become more likely foci of infection. The jaws begin to grow more rapidly about four years of age, as is evident in lengthening of the face, in spacing of the deciduous teeth and in extension forward of the previously receding mandible. This growth is so extensive that there is room for the first and second permanent molars to erupt behind the deciduous teeth. The six-year molar is the first permanent tooth to erupt and is the keystone for the permanent dental arch. Unfortunately, this important tooth is most susceptible to early and rapid decay. Because it often erupts before any deciduous teeth have been exfoliated and is difficult to see, many mothers mistake it for a baby tooth and neglect it until it has deteriorated beyond saving.

Orthodontic problems require consideration, but must be viewed with an appreciation of the correction which maturity may provide for the crowding, malalignment and malocclusion commonly present during the early period of the permanent dentition.

Pubescent changes characteristic of the beginning of adolescence begin to appear toward the end of this period. The physician must be alert to recognize them if he is to understand the basis for many of the complaints and problems and give appropriate counsel. Normal children may begin to manifest these changes as much as two years before or two years later than average expectancy. Clearly, children of the same age, but in such widely different stages of development, require different care and counsel.

#### ADOLESCENT PERIOD (see also p. 147)

This is the period in which the child "grows up" from childhood to manhood or womanhood. It is a period of profound changes in physical, physiologic, mental and emotional development. Endocrine and reproductive

organ developments result in sexual maturity, and other phases of growth and development are completed. It is difficult to define accurately the beginning of adolescence in the individual. Gains in weight increase in magnitude yearly from about five years of age, and the added spurt of adolescence may not be easy to demarcate except in retrospect. The rate of growth in height, however, which has been diminishing yearly from the time of birth, starts to increase again, and may be used as one of the indications of the onset of adolescence.

Figure 8 (p. 14) shows that gain in weight is relatively greater than gain in height during this time, and the adolescent tends normally to a stocky appearance, as he did in mid-infancy. The adolescent obesity which may result is important from both a physical and a psychologic standpoint. The effect on participation in sports and other activities, and hence on muscular development and body mechanics, may be profound; its effect on social adjustments and emotional life may be no less significant.

The gain in height is abrupt at the onset of adolescence and continues at a rapid rate for a year or two, and then decelerates with equal rapidity. Gain in weight persists for a longer time than that in height.

At all ages of childhood there are individual differences in the rates of growth, but these are far more important and confusing during adolescence than at any other period. Owing to the lack of conformity between developmental age and chronologic age, most children will deviate from their customary percentile positions temporarily at the time of their maximum adolescent growth. Each child, however, tends to follow a predictable pattern once the adolescent changes have been initiated.

Early-maturing subjects tend to exhibit greater spurts in growth than do those maturing late, but they terminate growth earlier. Hence the ultimate heights may not be very different from those of children maturing at a later age. In fact, early-maturing children who are very tall during prepubescence may be relatively short at maturity.

Food requirements and other needs will differ for those who mature at different ages: When late-maturing children are growing at their slowest pace, "average" children are in their period of maximum growth, and the most advanced have essentially completed it. Within each group, however, there will be

some who are naturally small and others who are naturally large, each of whom has a different growth potential. Furthermore, some adolescents are more advanced in one aspect of development than another; these asymmetries should be noted, since they may add to the stresses and misunderstandings of the period.

The tendency for girls to have more subcutaneous tissue than boys is exaggerated at this time, and obesity tends to be particularly disturbing to them. Boys, however, tend to develop much larger muscles. After growth in height has ceased and sex characters suggest that the boy is fully grown and mature he does not yet have the muscular development or, therefore, the strength of the adult. It is imperative that the adolescent receive adequate nutrition and have appropriate physical activity. The heart muscle may not develop so rapidly as the skeletal musculature, and the strapping, muscular adolescent boy may not have a heart as proportionately well developed.

In conformity with the law of cephalocaudal progression of growth, leg length increases rapidly during early adolescence, but slows down and ceases before growth of the trunk is terminated. Thus the adult loses the long-legged, gangling appearance of the adolescent. Girls become relatively broad-hipped from about the age of twelve, whereas boys grow rapidly in shoulder breadth from about the age of thirteen.

Skeletal size increases markedly in adolescence, especially in boys. Certain stages of osseous development parallel so closely secondary sex development that they can serve as an index of the degree of maturation: For instance, menarche usually occurs within six months after beginning fusion of the epiphysis and diaphysis in the distal phalanx of the second finger. In general, at the time of adolescence, girls are two years in advance of boys in osseous development and in other aspects of the maturing process.

The development of primary and secondary sex characters follows a natural sequence with great consistency, but there are differences in the chronologic ages at which different milestones are passed. Hence there is a wide range in the size or general appearance of the sex characters and the functional state of the sex organs of boys or girls of the same chronologic age, especially between ten and eighteen years of age. The nutritional, psychologic and social needs vary with the stage of adolescence. The development of sex characters is

a helpful guide by which to judge these needs at a time when chronologic age is an uncertain and often misleading index of expected growth and development.

The male primary sex organs are the testes, the epididymes, the seminal vesicles, the prostate and the penis. They are rudimentary structures in infancy and largely remain so until the onset of the adolescent period, when there is rapid growth until the sixteenth to the twentieth year. Prostatic secretion appears fairly soon after that gland has begun to enlarge, but mature spermatozoa are not usually found until fifteen or sixteen years of age. The capacity to reproduce is probably not present until general growth has become slow, after most of the epiphyses of the long bones have fused with their diaphyses, and when all the secondary sex characters are well advanced—sometime after the sixteenth year.

The development of the principal male secondary sex character, adult body hair, is a useful index of the development of less easily recognized but more important sexual attributes. The character and distribution of hair should be noted in four locations in the routine examination of adolescent boys. It appears first in the pubic region, about the time of the adolescent growth spurt, as fine, vellus hair, which changes slowly to a coarse, dense, pigmented type which finally curls or kinks. About the time when growth begins to decelerate, the pubic hair has spread laterally to the inguinal creases and upward to the pubic crest, forming the inverted triangle characteristic of adult female distribution. Toward the end of adolescence and appearing as a convenient index of approaching sexual maturation, pubic hair extends upward toward the umbilicus and outward to the femoral areas of the thighs to form the diamond-shaped distribution characteristic of the adult male. Some months after the appearance of pubic hair, axillary hair makes its appearance, and subsequently facial hair begins to grow. About this time, but often considerably later, the hairline of the forehead may begin to recede on either side, producing the laterally indented configuration of the masculine type. The extensive development of mature hair on the chest and extremities comes last of all and may continue well into adult life.

About the time of the appearance of axillary hair, some development of the breasts in boys may occur, with elevation of the nipples and occasionally a mass of firm tissue under-

lying a slightly full areola which disappears after a number of months. Change of voice does not begin until these sexual changes are fairly well advanced, and the voice does not usually acquire the deeper tone characteristic of the mature male until the fifteenth year. The entire pattern of secondary sex character maturation rarely takes less than three years for its development and may take longer. Boys who begin to mature early tend to pass through this period rapidly.

The female primary sex organs, the uterus, the ovaries and the vagina, begin rapid growth about the age of eight or ten years, but do not reach adult size until the age of eighteen or twenty. Secondary sex characters are useful indices of this development. Throughout adolescence the hips round out, owing to broadening of the bony pelvis and an increased deposition of subcutaneous fat. Usually the earliest signs of beginning sexual maturation are evident in the breasts: Between the tenth and twelfth years the areolas enlarge and tend to embed the papilla. The enlargement is occasionally irregular and may simulate a small tumor; parents should be assured that this is a normal phenomenon. Eventually the breast itself enlarges, incorporating the formerly elevated areola, but leaving the nipple elevated. Usually the breasts are moderately well developed at menarche. About a year before the first menstrual period, and when the breasts have shown their first areolar changes, the vaginal tissues become hypertrophic and grayish; the reaction changes from alkaline to acid, and the epithelial cells become cornified. Hair appears first in the pubic region above or about the labia and spreads medially and upward to the crest of the pubis and laterally to the inguinal region. Lack of body hair above the pubis accounts for the characteristically triangular pattern of adult female pubic hair. Axillary hair appears about six months after pubic hair, and each progresses from a downy to a coarse, curly type.

Menarche occurs about the time of the appearance of axillary hair, between eleven and fifteen years of age, most commonly about thirteen years. During the first year of menstruation, periods are often irregular or entirely missed; some girls may even require a longer time to develop regularity. These early irregularities rarely are significant. Dysmenorrhea and irregularity seem to occur more frequently in girls of a "masculine" build. Conception seems to be unlikely until a year

after periods have begun. Indeed, from studies of promiscuous girls, it appears that conception is uncommon before the age of sixteen and not probable until four or five years after menarche. Thus the end of adolescence in girls may be placed at about eighteen years.

#### FACTORS AFFECTING GROWTH AND DEVELOPMENT, AND CAUSES OF INDIVIDUAL DIFFERENCES

An attempt is often made to distinguish individual differences or aberrations of growth due to heredity from those due to environment or disease. Such a distinction can be made for only a few constitutional characteristics and developmental defects. In following the progress of a child one must recognize, so far as knowledge permits, those attributes which are primarily expressions of his intrinsic make-up: that is, his appropriate physical habitus and characteristic pattern of growth. One must also distinguish these from physical manifestations which denote interference with optimal status and progress. In making such distinctions one should never overlook the possible interrelations between these influences or the opportunities for improvement of the constitutionally inferior or handicapped person by correcting defects or improving environment.

*Heredo-constitutional factors* (see also p. 234) are primarily responsible for the wide variability in the manifestations of normal attributes, such as stature and physique, and for individual characteristics of growth patterns. Abnormal genes are responsible for certain specific anomalies, familial diseases and certain types of dwarfism. Congenital defects, however, are not solely due to these factors. Many occur more frequently in some families than in others, yet not necessarily in accord with the mendelian laws. It would appear that genes differ in expressivity; a genetic factor may predispose to a specific defect, but environmental circumstances surrounding the embryo determine to some extent whether the defect becomes manifest and the degree to which the abnormality develops.

Environmental factors undoubtedly affect growth of the ovum and of the spermatozoon before conception, and development of the fertilized egg from the moment of conception to the delivery of the infant.

The order of birth appears to affect the infant's size at birth, the average firstborn being lighter in weight than the second, and

birth weight tends to increase with increasing birth order. The linear dimensions of the firstborn are also somewhat smaller than those of the later born. Measurements of infants born in different socio-economic groups indicate that on the average the newborn of the poor are smaller in length and weight than those of the well-to-do. There is accumulating evidence that the nutritional state of the mother and her long-time dietary habits are in some way related to the rate of linear and ponderal growth during the fetal period and to the progress of maturation as evidenced by the stage of osseous development at birth.

*Environmental forces* play a much more important part in determining the course of growth and development after birth, especially during infancy. There are real differences in the average sizes of infants and children and in their average rates of growth in relation to the socio-economic status of the families to which they belong and to the general local environmental conditions. For example, white boys in the United States of professional and managerial class families tend to be taller and heavier for their age than those of unskilled and semiskilled class families. Since adequate diet depends in part upon family income, these associations are not surprising.

**Sex.** At some ages boys are so different from girls in size, rate of growth, physical proportions and stage of maturation that entirely different base lines of normality must be adopted. However, all distributions of data for the two sexes overlap, and individual subjects tend to show certain characteristics of the opposite sex. For example, broad shoulders, narrow hips, thin panniculus, angular contours and tall stature are primarily masculine characters, but are seen in varying degrees in many girls. So, also, boys may have narrow shoulders, broad hips, thick panniculus, rounded contours and short stature, which are characteristically feminine traits.

**Race or National Origin.** Anthropologists have described many physical differences between national groups; a familiar example is the tallness of the Scot in contrast with the shortness of the Italian. Racial and national characteristics undoubtedly have developed in the main from segregation within geographic areas and the consequent transmission of genetic traits through common ancestry. It seems probable, however, that common environment and customs have influenced many national traits to an important degree. When

such customs are changed, many supposedly racial characteristics begin to be modified. For example, short stature is characteristic of the Japanese people, but each successive generation of Japanese children living in the United States becomes more like American children in stature.

**Inborn Metabolic Errors.** Recognized inborn metabolic errors are relatively rare, but when they occur, they often retard growth by interference with various metabolic functions; they include such conditions as cystinosis, "renal rickets," oxaluria, hepatic glycogen storage disease and galactosemia.

**Endocrine Factors.** Endocrine factors undoubtedly play an important part in establishing many "normal" variations as well as many of the gross deviations of growth and development. The activities of the glands of internal secretion are determined in part by heredo-constitutional factors, but many disturbances of them may be acquired. Nutrition, disease and other environmental circumstances affect hormonal activities. The glands of internal secretion, especially the thyroid and the pituitary, are the principal mechanisms through which heredo-constitutional and environmental forces are mediated to bring about individual differences and major deviations in growth and development.

**Prematurity.** Premature infants, as a group, have an increased incidence of birth injuries, including cerebral damage, congenital malformations, anemia, rickets, feeding problems, and infections. All these can affect growth adversely and add considerably to the difficulties of an infant who is small at birth and who would probably require two years to catch up with his full-term colleague without these complications.

**Congenital Defects.** Congenital defects may be due to abnormal environment during the embryonic period, as well as to heredo-constitutional factors. A classic example is the multiple defects often found in the newborn whose mother had rubella during the first trimester of pregnancy. Furthermore, congenital defects not only are caused by prenatal environmental influences, but may also themselves interfere with fetal or postnatal growth in a variety of ways. If the defect is incompatible with prenatal existence, the fetus will be stillborn; if it is incompatible with extra-uterine existence, death will occur at or shortly after birth. Some defects are compatible with life, but severely limit physiologic activities and adjustments, so that death

will probably take place during infancy or early childhood, when illness or other circumstance imposes special strain. Thus the unfit are in large part disposed of by natural processes in early life. Many defects, however, interfere not with essential processes, but rather with the development of special parts or organs and hence with certain functions. Mental deficiencies, central nervous system defects, including blindness and deafness, skeletal anomalies and defects of the heart and blood vessels and of the gastrointestinal tract and the genitourinary system may all produce characteristic handicaps of varying severity. They provide a unique set of problems to physicians who care for children. For permanently handicapped children the period of growth and development is one of special hazards, but is often also one of great opportunities.

Although congenital defects usually manifest themselves by specific signs or effects, they may do so only by interfering with general growth and may be discovered only through intensive studies. Defects in the central nervous, cardiovascular, urinary or gastrointestinal systems may be discovered only in the search for a cause for failure to grow normally, especially during the first few years of life.

**Climate.** Geographic or climatic conditions and seasonal circumstances appear to account for slight differences in size, maturation and rates of growth of children of given ages. Children tend to grow more rapidly in height during the spring than in the fall, and to gain weight much more rapidly in the fall than in the spring. Changes in physical activities associated with the length of daylight hours and the conduciveness of weather conditions for outdoor activities possibly have much to do with the slowing of gain in weight during the spring and the increase during the fall.

**Malnutrition.** Nutritional factors, both in health and in illness, undoubtedly account for a large proportion of retardations of growth and development. Lack of food, unwillingness to take suitable foods when provided, improper utilization of foods because of physical defects and illness, all contribute to interference with growth. Specific deficiencies as of vitamins C and D result in characteristic deviations from normal growth, but general malnutrition, principally owing to lack of adequate amounts of calories and suitable proteins, is usually manifest simply by less than optimal growth. Thus an effective means of

dealing with the under-par, malnourished child, in whom a careful search reveals no specific defects, is to study and correct dietary habits. This is usually a difficult and time-consuming undertaking, because social, psychologic and habit factors are almost always involved. The mechanism by which emotional disturbances influence growth is not always clear: it may be by simple anorexia or may be through a more complex psychosomatic device.

**Illness.** Infections, such as repeated attacks of acute tonsillitis or a chronic disease such as tuberculosis, create malnutrition by decreasing the child's appetite, interfering with the proper digestion and absorption of food-stuffs, and by increasing the metabolic need for nutrients. They may depress the bone marrow, and the resulting anemia can deprive the tissues of adequate oxygen. Chronic or repeated infections are probably the most frequent cause of malnutrition in American children. Illness may also cause permanent damage to particular parts or organs. When the nerve supply or circulation of a part is interfered with, as in a limb paralyzed by poliomyelitis, that part will not grow normally. The outcome will, of course, depend upon the age at which the injury occurred, but will be far more deforming and crippling than if injury took place after growth had been completed. Some diseases cause distortion of growth processes which creates deformities, as, for example, rickets.

Since most diseases are short-lived and there appears to be an adaptive mechanism through which growth rates may be accelerated during convalescence, the transitory effects of many illnesses are usually not recognizable. Chronically ill children may be retarded in one or many ways, the degree being greatest when there is interference with important life processes. For example, dwarfism is more likely with chronic anemias, cardiac defects which cause chronic cyanosis, renal diseases which interfere profoundly with function, and so on. Any chronically ill child, however, is likely to be less well developed than had he enjoyed good health.

**Activity.** Normal growth and development depend to a considerable extent upon adequate physical activity. Although a bedridden child will grow, his progress will be affected by the imposed interference with activity. The effects will be noted especially in the muscular system, but others also occur. Children's motor development is greatly affected

by their habits of activity, particularly during the adolescent period, when muscles are normally growing rapidly. Malnutrition, fatigue and inactivity are closely related, and a suitable balance between rest and activity, appropriate for age and circumstances, is a basic requirement for satisfactory development.

**Trauma.** Injuries may retard growth and development, but the factors and mechanisms involved are not clearly understood. They appear to be multiple and may be emotional as well as physical; tissue repair may constitute a nutritional drain; appetite failure may result from fear and pain; love and affection may be deficient.

#### **EVALUATION OF PHYSICAL STATUS AND OF THE PROGRESS OF GROWTH AND DEVELOPMENT**

Evaluations of physical status and the progress of growth and development should be integral parts of the child's routine pediatric care. The health history should provide a picture of the child's physical state at successive periods and the characteristics of his progress. This history is usually difficult to elicit satisfactorily except for the recent past and therefore is most serviceable when obtained periodically. The physical examination should include observations and appropriate measurements, calculated to bring attention to any undesirable features of growth and development. The physician whose training and interest limit his examination to the search for evident pathologic changes will miss much of importance. When unusual findings are discovered, special studies may be indicated, such as roentgenograms, more detailed measurements and laboratory determinations, but subsequent physical examinations will usually be necessary to determine the significance of such findings.

The physician must often evaluate the significance of unusual features of physical status, such as short stature, extreme linearity of build, apparent obesity, small or flabby muscles, peculiarities of posture. He must also consider the significance of slow growth or retarded progress in various aspects of development. His first problem is to determine the accuracy of the complaints. If they appear to be justified, they must be considered in respect to their causes and their significance for health and well-being. The significance of possible unusual growth or development should be viewed not only from the stand-

point of the moment, but also from that of the child's future growth and physical well-being. The parent requires and should receive considered advice on these matters, but appropriate advice depends upon correct evaluation and proper understanding of unusual findings. Attention will be focused here upon means of evaluating physical attributes in relation to standards based upon normal occurrences.

The physician can readily recognize unusual degrees of variation and can describe a child after inspection as short or tall, fat or thin, and in respect to many other attributes. It is difficult by inspection alone, however, to be sure that a boy is tall for his age. Sometimes thinness makes him appear tall when in reality he is shorter than the average for his age. More importantly, a physician cannot judge the extent of growth between two examinations on the basis of clinical descriptions. For example, if he rates a boy short at six years and then considers him so again at seven years, the question remains unanswered whether the boy has grown an expected amount during the year or has failed to make good progress. Rate of growth is usually more important than actual size; progress cannot be evaluated without precise data obtained through serial measurements. Furthermore, these data must be evaluated in relation to appropriate standards derived from large groups of normal subjects of the same age and sex, which permit consideration of variability as well as average occurrences.

In Figure 13 (p. 18) two sets of figures are given below the normal distribution curve, indicating particular positions within the range of the distribution. The first figures are percentiles and indicate the expected positions of the third, tenth, twenty-fifth, and so on, of any hundred in order of magnitude. In this theoretic "normal" curve the fiftieth percentile represents an average and is at the peak or central point in the curve. The twenty-fifth and seventy-fifth percentiles are equidistant from the average and include between them half of the total series. Similarly, the tenth and ninetieth percentiles are equidistant from the average and include 80 per cent of the total, excluding on the left hand side the smallest ten and on the right side the largest ten in the series.

The second set of figures gives the average as the mean and expresses any given position under the curve in terms of the standard deviation from the mean. Standard deviations

below the mean are negative, and those above, positive. By this method the mean plus or minus 1 standard deviation encompasses approximately 68, and plus or minus 2 standard deviations about 95, of the hundred. These are the common methods for expressing the position of a measurement in relation to the variations normally encountered.\*

The percentile method of expressing position within a distribution is usually preferable in clinical practice to using the mean and standard deviation for two reasons: (1) The concept of percentile position is more readily understood and its location more easily found by one unfamiliar with mathematical concepts. (2) Some distributions normally show skewness to one or the other side of the mean (Figs. 15, 16), and percentiles are more accurate when applied under these circumstances.

The idea of percentile position is readily conveyed by the following hypothetical situation. One hundred boys of the same age are lined up in order of height, the shortest boy being at the left end of the line and the tallest one at the right. The short and the tall boys will readily be arranged in line because they will stand out from the group and differ appreciably one from the other. The middle or most nearly average boy will be hard to select because there will be many quite like him. Thus there will be a greater difference in height between the shortest and the twenty-fifth boy or the tallest and the seventy-fifth boy, than between the twenty-fifth and the fiftieth or the seventy-fifth and the fiftieth.

Tables giving selected percentiles for the principal measurements at each age and sex are given at the end of this chapter. When measurements for successive ages are plotted, the graphs (Figs. 19, 20) permit consideration of consistency in position at different ages as well as position at the moment, thus permitting evaluation of growth progress as well as growth status.

\* The term "normal" is used in this connection as a statistical concept to denote the range of values for a given measurement or determination usually encountered among like children under ordinary or given circumstances. It does not imply that all children falling within the total distribution or in prescribed positions of it are well or healthy or that those outside these limits are necessarily abnormal in any health sense. Unusual position within the range as well as outside it may be related to health, however, and values far removed from those of the "normal" range may be accepted as abnormal from the medical point of view.

Various factors must be considered before arriving at an opinion as to the significance of an unusual position of a particular child. The consistency of the positions held for a given measurement at successive age periods is important. One would be less concerned if a child held the same low percentile position in height at all previous ages than if he had held a higher position regularly up to a given time and then lost his relative position rapidly—an indication of failure to grow normally. The consistency between measurements must also be considered: Being uniformly small in all measurements is less likely to have health implication than being small in only one or several. For example, a child who holds a position close to the tenth percentile in weight, height and pelvic breadth is far less likely to be undernourished than one at the tenth percentile in weight, but above the fiftieth in the other two. Differences in position in various measurements, however, may be due to characteristics of body build and may be appropriate for the individual. A boy may be high in the range for height and low in that for weight because of a strong constitutional linearity in build, but he may also be so because of chronic malnutrition, faulty muscular development or other causes.

Sheldon developed a photographic method for describing and classifying individuals in respect to body build. He attempted to make the evaluation of build more objective by using measurements taken from these photographs in relation to three components, which he terms "endomorph," "mesomorph" and "ectomorph" (Fig. 18). All persons combine some degree of all three components of build, and most people are not strikingly dominant in any one. Although body type is primarily a constitutional attribute, it is not often clearly manifest in early life and appears to become fully established only in adolescence. When there is definite dominance, the pattern can often be recognized in early childhood.

The correlations between relative height and dominance of each component of body build are not close, each type showing a wide range from short to tall individuals. The chief relations between somatotype dominance and growth and development appear to be in speed of maturation. Endomorphs tend to mature early, whereas ectomorphs do so late. This results in the former appearing to be tall and the latter short in late childhood. The early

FIG. 18. Examples of dominance of the 3 types of body build according to somatotype classification of Sheldon.\* (Photos provided by E. E. Hunt, Forsyth Dental Infirmary, Boston.)

The principal characteristics of each of the 3 components of bodily constitution, some of which may be recognized in these photographs, are:

*Endomorphy*—relative preponderance of soft roundness throughout the body, with large digestive viscera and accumulations of fat, usually large trunk and thighs and tapering extremities.

*Mesomorphy*—relative preponderance of muscle, bone and connective tissue, with heavy, hard physique of rectangular outline.

*Ectomorphy*—relative preponderance of linearity and fragility, with large surface area and thin muscles and subcutaneous tissue.

THE CHILDREN'S MEDICAL CENTER, BOSTON - ANTHROPOMETRIC CHART

FIG. 19. Graphs for plotting selected measurements in infancy. These graphs as well as those in Figure 20 are based on studies conducted by the Harvard School of Public Health of white children in Boston of predominantly north European stock. Separate charts are used for girls, since norms for the 2 sexes differ appreciably.

These graphs serve for plotting weight and height measurements up to 30 months and head circumference up to 30 weeks. The percentile values on which they are based are given in Tables 7 and 9.

FIG. 20. Graphs for plotting weight and height in childhood. This graph serves to plot weight and height from 2 to 13 years of age (height is measured in recumbent position to 6 years of age).

Percentile graphs for plotting measurements against chronologic age are not as satisfactory for use after 13 years, owing to the wide age variability in the timing of maximum growth during adolescence. For graphs which extend to 18 years based on the percentile values given in Tables 8 and 10, see Stuart and Meredith: *Am. J. Pub. Health*, Vol. 36. Other percentile graphs covering various age periods are available from the Iowa Child Welfare Research Station, University of Iowa.

In evaluation of the measurements of the 13 year-old child it is usually possible to recognize by the appearance of secondary sex characters those children who deviate from expected percentile positions because of early or late pubescence.

termination of growth in the former and the long continuance of it in the latter tend to lessen this difference and sometimes to reverse it in the adult.

The particular pattern of growth for a given child, as demonstrated graphically on charts such as those illustrated in Figures 19 and 20, may differ markedly from what might be considered "normal" in the sense of "usual" and yet be appropriate for him. Children manifesting unusual trends in growth should be followed closely, but not necessarily with concern. Such trends may have serious significance, but they may also reflect intrinsic differences in individual growth patterns or merely transitory responses to diet or other circumstance. Infants on permissive feeding regimens, for example, frequently rise far above their customary channels for weight, or weight and length, only to return after a few months to their former channels. Some children, particularly during the preschool or early school years, gradually drift in one or more measurements from a low to a high position or the reverse. Most children, as noted previously, digress sharply but temporarily from their previous channels on these charts at the time of rapid adolescent growth.

Many methods devised for the use and interpretation of body measurements differ in various ways from the percentile one described here. Some are basically the same, as, for example, the charts prepared by Jackson and Kelly. Some are different in principle and may be used to advantage in conjunction with the percentile graph method in order to reveal a different aspect of measurement relationships or the same aspect in a different way. For many years the most widely used height and weight measurements were the tables prepared by Woodbury for infants and pre-

school children and those by Baldwin and Wood for school age children. These give the average weight for each sex by age and height. Faber later prepared a similar type of table giving a range of weights rather than the average weight for each age and height, a preferable procedure if height-weight relationships are to be considered in this way. Pryor carried the concept of an appropriate weight somewhat further by preparing separate tables for each sex and age which give expected weight for each height under several different categories of pelvic (bicristal) breadths.

Wetzel constructed two charts (grids) for evaluating growth and development, one for infants, the other for children. The latter has been used principally with children of school age. One graph on the left of the chart provides for plotting weight against height on double logarithmic paper. Straight channels, representing different types of physique or body build, traverse the graph from lower left to upper right. These are crossed at regular intervals by parallel lines representing development levels. These lines extend to a second graph on the right which contains percentile developmental curves (auxodromes).

No single method of using measurements affords a short and, by itself, a reliable means of evaluating growth. The physician must understand the basis and limits of the method or methods he uses and must apply his knowledge of the general progress of growth and normal variability to the interpretations drawn from any method. The student, therefore, is urged to practice the application of at least one method which he has studied thoroughly and to continue its use as an essential part of evaluation of his pediatric patients.

## TABLES OF NORMS FOR USE AS REFERENCE STANDARDS IN THE EVALUATION OF BODY MEASUREMENTS

Table 9 gives percentile values by sex and age for weights and lengths from birth to five years of age. Table 10 gives the same from five to eighteen years. All weight values are expressed in pounds and kilograms, and length or height values in inches and centimeters. In order to simplify presentation, pounds and inches are given to the first decimal place. As noted on page 43, the number of percentile indicates the position which a measurement of the given value would hold in any

typical series of 100 children. Tables 11 and 12 present in a similar manner values for other measurements, selected on the basis of clinical usefulness. In these tables measurements are given only in centimeters.

The norms for all measurements from birth to five years of age (Tables 9, 11) are based upon repeated measurements at the ages given of a group of white children of north European descent living in or near Boston. These children were considered to be free

from important defects or chronic diseases. Although they belonged for the most part to families in the lower economic brackets, they had the advantage of regular health supervision. The norms for all measurements from five to eighteen years (Tables 10, 12) are based upon similar studies in Iowa City. The children in this group were almost entirely of northwest European descent and predominantly from the professional and managerial classes. Although this places them in a somewhat higher economic classification than the Boston children, comparison of the distributions for measurements of the two groups at the same ages shows them to have been similar in physical dimensions.

The norms given under specified ages are not composite groupings of measurements of children at intervening ages, but are based upon children at or near the age in question. Norms are given at three-month intervals from birth to eighteen months and at six-month intervals thereafter. In referring a given measurement of a child to the appropriate table the child may be considered at an age given in the table if close to it; otherwise halfway between two given ages.

Norms for sitting height are useful in the study of children with disproportions or abnormalities of growth; they are presented in Table 13.

## TECHNIQUES FOR TAKING MEASUREMENTS

The first consideration in using these tables is to be certain that the measurements to be referred to them have been taken according to the techniques used in obtaining the data they present. A slight variation in technique may cause a considerable difference in the percentile rank in which the measurement will fall. In hospital practice certain variations from the techniques described are occasionally required by the condition of the patient, but these should be noted and allowance made for them in interpretation.

Certain differences in procedure are necessary or desirable in infancy. These do not alter the percentile position of the measurement if the physician is careful to use the correct procedure for age. For example, norms for recumbent length are given up to five years because of the difficulty of securing reliable measurements of standing height under this age. Standing height is generally a more convenient measurement after five years of age, so that norms for it are given from this

age. If recumbent length must be used after six years of age, the value obtained should be reduced by 1 cm. before placement in the range for standing height.

Measurements should be taken without clothing, though after six years of age shorts or some other undergarment is permitted.

**Length.** Body length, measured in the recumbent position, should be used to five or six years of age, depending on the standard of reference used. The child lies on a firm table with a measuring stick at least 125 cm. or 50 inches long inserted along one edge. The soles of the feet are held firmly against a fixed upright placed at the zero mark. A movable upright crosses the table above the head and is brought firmly against the vertex.

**Height.** Stature, or standing height, should be used at five years and thereafter. The child stands erect against a firm upright containing a 2-meter or 2-yard stick or other accurate measuring device. A wooden headpiece having two faces at right angles is placed firmly on the head against the measuring scale. The child's heels should be closely placed, and heels, buttocks, upper part of back and occiput should be against the vertical upright, the arms hanging at the sides in a natural position. The external orifice of the ear and the lower border of the bony orbit should lie in a plane parallel with the floor.

**Pelvic Breadth.** Pelvic, bi-iliac or bicristal breadth is the distance between the lateralmost points of the iliac crests of the pelvis, including the overlying soft tissues. It is conveniently measured on the infant and young child by spreading or obstetrical calipers with the infant recumbent. The norms up to five years are based upon this procedure. After five years, to conform with the norms in Table 10, the pelvis should be measured with a broad sliding caliper applied over the crests of the iliums, the child standing and facing the measurer.

The points of spreading calipers should not be pressed deeply into the soft tissue; whereas, with sliding calipers, the maximum pressure without causing pain should be applied. If these precautions are followed, measurements taken by the two instruments will not differ appreciably; otherwise, measurements by spreading calipers will be somewhat smaller than those by sliding calipers in obese children.

Measurements of circumferences may be taken with either a steel or linen tape marked in millimeters. The latter is more convenient with infants, but is subject to shrinking and

stretching and should be checked frequently against a meter stick.

**Head Circumference.** This measurement is particularly valuable under one year of age and need not be taken after three years. The tape is applied firmly over the glabella and supraorbital ridges anteriorly and that part of the occiput posteriorly which gives the maximum circumference.

**Chest Circumference.** Up to five years of age the norms for this measurement are taken with the child recumbent. The girth of the thorax is measured with the tape at the level of the xiphoid cartilage or substernal notch, and in a plane at a right angle to the vertebral column. The reading is made in midrespiration. At five years and thereafter, for reference to Table 10, chest circumference should be taken with the child standing in a natural manner, facing forward, and the arms slightly away from the sides of the body. One must be sure that the child is not holding his breath with lungs inflated.

**Abdominal Circumference.** This measurement is taken to three years only and is of value principally in recognizing chronic intestinal disturbances. The tape is applied with light pressure in the plane of the umbilicus with the infant recumbent.

**Leg Circumference.** This is the maximum circumference of the calf and is taken after five years only. The child stands with his feet

several inches apart and his weight equally distributed through both lower limbs. The tape is passed around the calf and adjusted until the maximum girth is obtained.

From Studies of Child Health and Development, Department of Maternal and Child Health, Harvard School of Public Health.

The figures for the several percentiles of each measurement at 5 years differ slightly from those given in Table 12 for this age because they were obtained from a different population of children.

The figures for the several percentiles of each measurement at 5 years differs lightly from those in Table 11 for this age because they were obtained from a different population of children.

The measurements in this table are from studies by and are reproduced by courtesy of Howard V. Meredith, the Iowa Child Welfare Research Station, The State University of Iowa.

The data were collected 1930-46 on Iowa City boys of northwest European ancestry in attendance at the University of Iowa experimental schools.

Technique for measuring sitting height: The child sits on a horizontal bench about 30 cm. high at the base of a vertical measuring rod. The knees are flexed and spread apart and the ankles crossed, and the sacral, upper thoracic and occipital regions are in contact with the scale. The measurement is taken as in height. This measurement is of value when the question of disproportionate growth is being considered: disproportions will be evident when the percentile positions for standing height and sitting height differ appreciably.

The measurements in this table are from studies by and are reproduced by courtesy of Howard V. Meredith, the Iowa Child Welfare Research Station, the State University of Iowa.

# MENTAL AND EMOTIONAL DEVELOPMENT

Many children present problems purely of personality or faulty social adjustment; emotional reactions often complicate or are complications of physical disorders. Actually, the child grows as a whole with an intricate interplay of physical, mental and social factors. The following summary of intellectual and emotional development will rarely be found in such pure culture in the individual child.

Mental and emotional development is always in a state of flux. The physician must form the habit of noting mental and emotional symptoms even more than physical ones as part of the child's progressive development. The newborn infant lives a vegetative existence which depends largely on functioning of the spinal cord and the lower levels of the midbrain. Soon, however, he begins to use certain facilitated pathways in the nervous system which link the actions of various muscle groups. The more deeply patterned of these pathways are termed "prepotent reflexes," a term which has superseded its predecessor, "instincts." The higher cerebral levels soon begin to function, and environmental influences then rapidly increase in importance in modifying behavior. Many people, however, fail to recognize that through the "psychomotor tensions" the various factors of environment have made definite impressions from the day of birth. This is the term for the way we talk, walk, hold the baby and cuddle him, the nuances that accompany all human interrelationships. Nothing is more important than for the physician to realize that the tension of each voice in the home, the furrowed or serene brow in the office or at the bedside—all mean more to the child than whole volumes of words.

## HEREDITY AND ENVIRONMENT

**Heredity.** The relative importance of heredity and environment in determining behavior is not known. The understanding of human heredity is so incomplete that the physician should assume every behavior problem to be of some environmental origin. On such a basis prevention and treatment may be considered possible. Of course physical characteristics and many physical defects cannot be changed. This is also largely true of intellectual defects. There are, however, means for improving the lot of many children. The care of the handicapped child and of those chronically ill has

become one of the great responsibilities of pediatrics.

**Environment. Family experiences.** The child's environment begins to crystallize long before he is born. His parents, in their teens, began dreaming about what their children should have or should be. No two children of any family have the same relationship to parents; with each new child the family pattern undergoes a change.

The family experiences of the child, owing to his susceptibility, are the most determining of his entire life. The physician must know what the parents are like, the siblings, and what each child means to the family. Is each child accepted for himself, an individual loved because he is what he is? Or are the parents overcome with resentment because a girl is not a boy? How is the newborn accepted by various members of the family? These and many other factors are important in the development of the child's emotional pattern.

**Ancillary factors.** The physician, nurse and school teacher have significant roles. Each is considered more or less a magical person and is listened to by parents, who accept his guidance with little question because he is an expert. This being so, the physician, as well as other advisors, must be aware of the implications for good or bad every time he gives advice. A fair share of behavior problems are iatrogenic, brought on by well-meaning physicians who do not always understand human behavior and who make suggestions which turn normal developmental patterns into abnormal ones. For example, messy eating habits, normal in the preschool child, may be bottled up by rigorous attempts at cleanliness, with the result that the child becomes not only a finical eater, but also compulsively clean and even constipated. Or a misinterpretation of deliberate withholding of feces, if treated by mechanical manipulation of the anus, can result in obstipation.

**Neighborhood.** When the child is about two years of age, the neighborhood becomes an integral part of his environment and a powerful force in molding his personality. He needs opportunities to meet other children with whom he may play in a small group under supervision of a responsible adult. As he grows older, the group can be larger and the supervision less individual. The child

graduates from playing in his or a neighbor's backyard with a companion or two to larger group activities which require larger play areas and some degree of organization.

**Nursery school.** The nursery school can assist the preschool child to grow up. Unfortunately there are many misconceptions about its usefulness and purpose. The good nursery school provides the preschool child with socialization opportunities which help him to become independent of his parents in a healthy way; it also provides opportunities to play in ways which many homes cannot tolerate because of his messiness and destructiveness. A good school helps parents as well as children by individual guidance about behavior. Early signs of maladjustment may be detected and steps taken to prevent further development of behavior problems. Parents can see that their children have many characteristics common to others of the same age and thus are reassured that development is proceeding as it should. *Not every preschool child needs nursery school experience.* It is particularly helpful to the only child and his parents, or when living quarters are cramped and inadequate. The physician should not advise concerning a particular nursery school until he has visited it and found out its general philosophy.

**Grammar school.** The child from six or seven years of age onwards is required by law to attend school unless there are physical or mental handicaps which excuse him. School has so many advantages that every attempt should be made for even the severely handicapped to have this opportunity. The school-age child is a "natural" to learn, because of his curiosity about everything. He learns best when he is with people who understand and love him and are skilled in bringing out his natural abilities. School also offers relationships with adults with whom to identify as the child fashions his own image of an adult. Where parents served first, teachers now take over. Like the physician and the nurse, the teacher needs to know that he is used by growing children as a model. In his own age group the child finds protection as well as stimulation. He wants to be like others, and fashions himself after his schoolmates; joining the gang or group multiplies his strength and permits him to do things he could not do alone. Here he can be both a follower and a leader. Behavior problems may arise anywhere in the chain of school experiences. Inability to learn, anxiety of competition, fear and

resentment against a teacher who does not understand, withdrawal from the group owing to feelings of difference or fear—all are examples of behavior difficulties brought to a physician. Every school should have on its staff a physician and a nurse, and probably a social worker, who, with the teacher, can detect a child who is in trouble and introduce measures to help him. A school physician thus becomes more than one whose role is making periodic physical examinations or checking skin and nose and throat at morning roll call. This physician needs a close working relationship with all members of the school staff, as well as with the child's family physician. When problems appear in a child, he should also have an understanding of the home life, and the child should be thoroughly studied physically, mentally and socially.

**Recreation.** Although school curriculums should provide time for supervised play during school sessions, each child needs additional time to play. School yards and buildings should be community resources for providing recreation to all members of families.

**Religion.** Religious education and worship are important forces in the development of children. The child of four or five is eager to go to church school, because most children attend by that age. He may be repelled if his religious experiences are too fear-inspiring. The school-age child has a strict conscience, based on fear of disappointing parents and other people. He may become so guilt-ridden by pressures in religion that his behavior indicates emotional disturbance such as compulsive acts (penance) and protective rituals, or extreme goodness and feelings of unworthiness.

## REFLEX ACTIONS AND LEARNING,

The reflexes are important because the time of their appearance is an indication of the child's development and because the manner of their use indicates the intactness of the nervous system. Reflexes tend to develop in an orderly fashion. This development is not in order of complexity, since, for example, swallowing is present even before birth. Those reflexes most necessary to life develop earliest. Usually the development proceeds in an outward direction; e.g., the reflexes of the hands and feet develop later than those of the arms and legs. A common mistake is that of urging the use of pencils and other objects requiring fine finger coordination before the

child has familiarized himself with the coarser coordination of the arm and forearm. Much clumsiness in writing and the ever present complaint of destructiveness are due to failure to fit toys to the normal progression of development.

In general, failure of a reflex activity to develop at the proper time indicates retardation which will become more evident in the succeeding months when other and more important reflexes should appear. Weakness or absence of a reflex suggests a lesion in the peripheral reflex arc; exaggeration and jerkiness, a lesion in the central nervous system.

**Progression of Motor Development.** (See Table 7, p. 34.) Behavior which began as a reflex progresses to a more complicated pattern through repetition, learning (from stimuli within the self) and teaching (stimuli from outside). An example is that of grasping—a reflex present at birth which becomes integrated so that by three months it is purposeful and voluntary, and by six months a bottle or rattle will be grasped. By about eight months simple objects can be manipulated, and simple movements imitated and the infant will “pat-a-cake” and play “peek-a-boo.”

When lying on his stomach, an infant of a few weeks of age will lift his head momentarily, but he does not have this ability when lying on his back until about three months; by five months he will roll over. Muscular power and coordination increase, and he will sit erect without support by six or seven months, creep by seven months, stand by eight or ten months, and walk soon after. He will usually be able to run at two years and will walk backwards or go downstairs alone by thirty months.

This progress depends on the functioning of well patterned reflex pathways and training; the pleasure obtained from these activities is a reward which fosters their continuation. It is, however, necessary to recognize the orderly progression of reflexes and the child's readiness for certain behavior which is individual with him, so that the child is *allowed* rather than forced to develop.

**Learning.** Children learn if they have the proper physical equipment such as intact sensory systems, and if they have the opportunity and the proper teaching. There are many theories of learning, but all agree that each child has to do his own learning.

Many repetitions of an act determine pathways in the nervous system, so that a pattern of response occurs when the appropriate stim-

ulus is given. These acts have the appearance of reflexes, but are termed “habits”; they differ from reflexes chiefly in the fact that they are more easily modified or are voluntary. These pattern responses are also called “conditioned reflexes,” and are believed by some to embrace a large part of the child's learning. Children may learn the use of the toilet by conditioning. The trouble with this kind of learning is that it can break down when the setting is changed even slightly. A different bathroom from the accustomed one may interfere with defecation.

Learning through teaching whereby the child understands and has feeling for the behavior learned is more useful and longer lasting. That is why children who learn by doing get a feel for their actions and retain what is learned so that they are able to apply it correctly when called upon. This does not mean that learning cannot be hastened by drill and practice.

Four principles or factors apply to learning by the child. These are (1) emotional and physical ability; (2) desire to learn; (3) previous experiences; and (4) active participation. For example, he will learn to read when he is ready (not all children are ready at six years), when he has the interest, and when he gets pleasure from the act so that he wants to repeat it and one day do it by himself. In a general way, high or low levels of intellectual ability are transmitted to children by parents of corresponding levels, but there are many exceptions. However good a child's native ability is, it can be helped or hindered by environmental factors.

## SENSORY DEVELOPMENT

The protopathic sensations are well developed at birth, although poorly localized. They include those of pain, temperature, touch and equilibrium, the kinesthetic sense of muscles and joints and the various sensations of discomfort or satisfaction in the functioning of the gastrointestinal and urinary tracts.

**Special Senses. Smell and taste.** These two senses are present at birth. By two or three months of age, taste is acute, and the infant will notice a change in the amount of sugar in a formula or a change in type of milk mixture and demonstrate pleasure or displeasure. The infant explores his environment in this way and it is normal for him to put everything into his mouth. This exploratory activity with the mouth, along with

much sucking, usually persists through infancy and is a part of normal development, not an activity to be curtailed. Persistence of "mouthing," drooling or excessive sucking of fingers or objects after the age of three years should suggest a study of the child's mental health.

**Sight.** In the first few weeks of life sight is limited to the ability to distinguish light from darkness. Bright light causes contraction of the pupils and closure of the eyelids. By about one month the eyes will follow bright objects; they will turn toward the direction of an unusual sound, and the eyelids will close if objects are brought near the eyes. By three months the infant will recognize his bottle or a similarly familiar object, and the movements of the eyes are usually coordinated, although incoordination may persist for several months longer. By five or six months visual impulses are stored up (memory), so that there is increasing recognition of familiar faces and objects; about this age the emotional response of fear begins to show a stereotyped pattern, with crying at the sight of strange faces and objects. Infants are normally farsighted.

**Hearing.** A few days after birth, hearing is acute, especially for high-pitched noises. Musical notes may be pleasing by four months of age; even earlier, some infants are soothed by a soft voice or a lullaby. Serious defects in hearing are often overlooked because of the custom of accompanying words with appropriate gestures.

## SPEECH

The development of speech is one of the best measures of intellectual progress; though environmental factors play a role in acquiring speech, undue delay in its development is a bad prognostic sign. The important consideration is not the clarity of speech, but whether the child tends to use a distinctive sound or symbol for an object. For example, does he consistently make the same sound to indicate a chair even though the word "chair" is not distinctly enunciated?

The relation of environmental factors to speech is not predictable. Thus a child who is constantly associated with adults is often precocious in speech. Less frequently these same conditions retard speech, since the child need not learn to enunciate distinctly when oversolicitous adults fulfill his needs without his asking. Often twins will show retardation in

speech, since they have learned to understand each other by other means.

## EMOTIONAL DEVELOPMENT

In comparison with the knowledge of physical growth, little is known about emotional development. There is unquestionably an ordered emotional development just as there is an ordered intellectual and physical development. There are, however, no standardized methods of determining the normality of a child's emotional growth, although there do seem to be distinct phases of development. Gesell and co-workers have devised mental tests which assess performance and behavior at different stages of infancy and are helpful in differentiating the intellectually normal from the mentally defective child. Other tests such as the *thematic apperception tests*, the Rorschach being an example, have been devised as short cuts in appraising affective development and emotional disturbances, but the complexities of personality require more detailed investigation.

Although the various concepts of emotional development disagree in some respects, there is agreement that the human personality is the product of a dynamic process which is ever changing and growing as the body develops and matures. This process may be regarded as an interplay of forces in the child with those in his environment. The experiences of early life are important in forming the subsequent personality structure. For this reason the role of the child's physician as a guide is of paramount importance.

Of the influences which determine behavior, probably most important is that of the mother, or her surrogate, who cares for the child from birth on. If the mother is able to respond to him naturally, accepting him as he is with love and permitting dependency without fostering it, she will naturally become aware of his needs.

Feeding of the infant by the mother permits early establishment of a good interpersonal bond when the procedure is satisfactory to both of them. Contrariwise, feeding practices which are forced will foster problems in various areas of behavior. The dependency which the infant shows toward his parents, particularly the mother, is gradually replaced by independence and self-sufficiency. The beginnings of such emancipation are seen around the age of two years. This psychologic weaning is not uniform; it probably begins

with self-feeding and ends after adolescence, but its progress and final resolution vary. Some parents attempt to speed up emotional development and are abetted by professional persons who mistake physiologic dependency for immaturity and interpret cuddling as coddling. A child who is pushed psychologically beyond his depth or faster than his natural rhythm will become tense and anxious. On the other hand, when parents try to slow up progress, the normal child will throw off the yoke of oversolicitude and pampering.

## INTELLECTUAL GROWTH

For practical purposes, intelligence may be defined as associative memory. Mere memory, however, is not intelligence, and the child who recognizes different makes of automobiles or remembers innumerable telephone numbers is not necessarily intelligent.

A distinction must be made between "formal intelligence," which is used in academic learning, and "contentional intelligence," which may be defined as common sense, shrewdness, astuteness or the ability to get along with people. Probably both types of intelligence are somewhat determined congenitally, education and environment playing an important role in altering them. Much confusion has arisen over failure to recognize that the so-called intelligence tests do not measure contentional intelligence. At present there are no standardized tests for this important function, and the physician must use, as in the field of emotional development, subjective judgment of the child's ability in this respect.

**Intelligence Tests.** These tests measure only formal intelligence. Though they do not measure to any significant degree the ability to make social adjustments, they do reflect the capacity for learning.

The intelligence quotient (I.Q.) is obtained by dividing the mental age (M.A.) by the chronologic age (C.A.) and multiplying the result by 100. Thus if a child of eight years of age performs the tests which an average child of ten years is able to perform, his I.Q. is 125; whereas if he only performs the tests which are expected of a six-year-old child, his I.Q. is 75. The most widely used test in this country is the Stanford revision of the Binet-Simon tests. The I.Q. remains practically constant, but in children under six years of age it is only of approximate prognostic value. Emotional disturbances such

as anxiety, fear and worry, and physical factors, such as fatigue and inadequate nourishment, may modify the rating.

Though only approximately correct, an I.Q. over 140 (genius) signifies that there should be amplification of the school curriculum; 120 to 140 (very superior intelligence) represents capability of professional school attainment; 110 to 120 (superior intelligence) indicates good college potentialities; 90 to 110 (normal intelligence), good high school ability; 70 to 90 (dull normal intelligence), good sixth to eighth grade ability; 50 to 70 (moron), that school work will be unsatisfactory, but there is the ability to do simple repetitive types of manual work; 30 to 50 (imbecile), that there should be permanent placement in an institution (most good school systems exclude children with an I.Q. below 50 as uneducable); below 30 (idiot), that there is no capability for self-care. Although tests should be performed only by those familiar with their interpretations, Table 8 (p. 35) can be used to form a rough estimate of intellectual development.

Inequalities between demands or expectations of parents or teachers and the ability of the child are frequent sources of difficulty and lead to such symptoms as nausea, anorexia, stammering and tics and to such behavior difficulties as irritability, rebelliousness, truancy and seclusiveness. Faulty school placement also is the source of such behavior disturbances. The physician need not be an expert in education, but he should know first-hand the child's school and its demands. The child's I.Q. is important in relation to that of the general average of his class or school. Children with I.Q.'s only a little below the average are under much more strain than those whose ability is sufficiently low so that they are not expected to keep up. The physician must look at the "whole child" and recognize that a child of seven years with an I.Q. of 130, but without comparable development in other respects, is different from one of seven years who has the physical, emotional and intellectual development of a child of nine years. The former should be kept in second grade with an enriched curriculum; the latter is better in third or, on occasion, even fourth grade. School promotions are not problems for the physician, but recognition of the related difficulties may serve to explain certain baffling and stubborn behavior disorders.

## MENTAL HYGIENE

The role of the pediatrician in helping parents and children in personality disorders, psychosomatic illness or deviant behavior is not always clear. By training, experience and the limits of his practice the pediatrician seldom is prepared to serve as a psychiatrist. However, he and the general practitioner most often see psychologic problems in their incipency. For this reason he must assume some kind of role. Ideally, he should have a working knowledge of growth and development and of interpersonal relationships and should incorporate psychotherapeutic principles with the diagnostic study and treatment of each patient.

### A WORKING HYPOTHESIS OF BEHAVIOR\*

There are a number of theories of behavior; disagreement among the proponents of the various ones has delayed acceptance of mental hygiene concepts in medicine. The pediatrician who takes time to listen to parents, carries out his examination in an individual, careful and humane manner, and then patiently and objectively attempts to evaluate the results, practices mental hygiene. For guidance and teaching the physician may look to persons who are specially trained in medical psychology and psychiatry. Insight which comes in this manner is preferred to the so-called common-sense approach, which may sound reasonable, yet in practice too often turns out to be highly subjective and often irrational.

It is possible for the physician to have a practical yardstick to measure the behavior of many of his patients. In a number of instances, however, help of a psychiatrist or psychologist will be necessary.

The child comes into the world with certain "raw drives," e.g., the compelling one of the desire for food. Soon society begins to place barriers in front of this desire and to frustrate it—"you can do so and so if . . ." This type of frustration produces emotions, and emotions are the driving force for behavior of any form, be it socially acceptable and useful or socially condemned. There is, on the one hand, the orderly sequence of biologic and instinctual growth and development, and on the other the laws of social order. Periodically they meet in conflict, setting up emotional reactions in the child. There should be no attempt at destruction of

the "raw drive," but, instead, modification in keeping with cultural attitudes so that the resulting emotion will be optimally healthy and will permit the child both to experience his feeling and to get release in a way which is satisfactory to him and to society.

### EMOTIONAL GROWING PAINS

There are many traits of behavior in childhood which are part of healthy growing up, but are unacceptable to adults. They are characteristics which the adults also have, but wish they did not. Adults would like their children to be free of them and become upset when they are manifest.

**Jealousy.** Parents worry because children demonstrate jealousy, failing to realize that it is a normal reaction. In part it represents a self-protective device. For example, the arrival of a new baby is threatening to other children in the family, who become jealous of their status in the family. Rivalry is frequently an accompanying attitude and grows out of a wish to be recognized and to win one's share of attention, admiration and love. These feelings may also exist between playmates and classmates in school. When a child is unusually jealous, his parents should consult a physician, who may do much to reduce the tensions which seem to threaten the child. The meaning of the behavior must be sought, rather than a direct attack made on the behavior itself. Feelings of jealousy and rivalry are sometimes fostered by parents in an attempt to encourage a child to increase his efforts at learning or in improving his behavior in general. When children cannot successfully meet competition, they may be forced into a variety of behavioral characteristics which may include jealousy and a whole constellation of disturbing traits.

**Fear.** Fear is useful if it is transmuted to caution and prudence. Often, however, in conditioning the child to be cautious of fire, hot stoves, traffic hazards, strange dogs and the like, parents become disturbed when the child shows too much caution about things which they think he should not fear. Fears may be taken up almost as if by contagion when parents themselves are frightened. The physician will often be consulted about such problems as fear of sleeping in the dark, fear of other children or fear of going on errands alone. In many instances the parents have made such an issue of certain fears that what was a natural caution is fixed as an overpowering fear. Fortunately, most children

\* See also page 73.

rapidly lose unnecessary fears as they make contacts with other children.

Fears which are irrational and so severe that they interfere with normal activity are more properly termed anxieties. It is normal for anxieties to appear in all children in response to certain experiences. The young infant who in the first half-year of life does not seem to mind when his parents leave him, suddenly at six to eight months of age develops anxiety whenever they leave. At this time he also becomes anxious at the sight of strangers. Knowing that certain anxieties tend to develop at particular ages will be reassuring to parents and will help them to avoid situations which may intensify the anxieties. If a child must be separated from his parents, as in hospitalization, he should be prepared for it and the separation should be as brief as possible. Every effort should be made to maintain family contacts by writing, telephoning and visiting as frequently as possible.

The causes of anxiety are not always easy to ascertain, since they are frequently subconscious and part of defense mechanisms. For example, a child who has done wrong feels guilty and develops feelings of anxiety and fear of punishment. As children grow older and gain mastery over many of their impulses, their sense of reality becomes more mature and their tendency to become anxious is modified. Adequate maturation depends particularly on the relationship with the parents. The child needs to feel that they will go on loving him, despite his misdemeanors. Children frequently feel anxious about new experiences, and at these times particularly need encouragement and support. A sense of security fostered through many years of parental affection and confidence is the best protection against the development of abnormal anxiety.

**Anger.** The emotion of anger usually disturbs parents more in the way it is manifest than in its mere existence; many recognize it as a useful and protective mechanism. In early life the child shows this emotion readily, and temper tantrums are a common response to frustration in the first decade. After that age the child may hesitate to display this emotion because of fear of social reprimand.

Temper tantrums are violent physical responses accompanying anger. Sources of the emotion should be sought. When the child uses the tantrum as a device for gain, the question must be raised why this is the method of choice. An effective method of

managing a temper reaction is that of disregarding it. On occasion, holding the child (a difficult physical feat!) to quiet him, rather than for punitive restraint is recommended. The physician must never forget that anger arises justifiably when a child does not receive something which he actually needs or feels is due him, or when he is told to do something beyond his capacity. When the child at any age consistently feels and expresses anger of an unusual degree, or when he seems too passive, medical and psychologic appraisal is indicated.

**Stealing.** Young children do not naturally know about the rights of private property. They may help themselves to articles which belong to others; this is not stealing. As the young child's own property rights are acknowledged by parents and protected by them against the acquisitive tendencies of other children, the child gradually becomes aware of what is his and what belongs to others. He may occasionally take things from others without their permission, and society labels this as stealing. The causes of such behavior are many; for some children this constitutes a game, as if to see "how much one can get away with." Others steal in order to acquire material things which they seem unable to get by other methods. Stealing which persists, which is more than occasional and becomes more or less habitual, constitutes psychopathic behavior. In such instances psychiatric assistance should be sought.

**Lying.** Many parents have forgotten how they transmuted their earlier experiences into what they now term diplomacy, or white lies, or keeping up a front, or not making trouble by telling everything they know. Parents should distinguish between the make-believe which every child has and lying. The child does not distinguish till the school years. His first lies may be natural defenses when pressured by adults. Most children tell the truth until it is uncomfortable for them to tell it, when they begin to distort. "Make-believe" which the child cannot distinguish from reality, and persistent defensive lying are indications that something is going wrong and that a thorough evaluation of the child and his environment is necessary. Perhaps referral to a child guidance clinic should be considered.

**Summary.** The preceding paragraphs are illustrative of the more common problems involved in transmuting what we have termed "raw drives" into socially useful and acceptable modes of behavior. In general the physi-

cian will find that parents make three mistakes in this field: (1) Many do not understand the naturalness of these raw drives. They are worried over the degeneracy of their children. They bring them to the physician because they steal, because they are jealous and because they are always under foot, without realizing that it is precisely these impulses of acquisitiveness and ambition, and the wish to be in the center of things, that make the world go round. Such parents should be helped to remove the moral implications from the drives, and to understand that, properly directed, these attributes are the children's best assets. (2) Many parents try to convert these impulses too rapidly. Thus they expect children to earn all their spending money, often when they are too young or are incapable. Children who are exhorted to get better grades in school than they are able often resort to cheating, to sulking or to stealing money with which they can buy social favor. (3) Many parents have never progressed much beyond the childish drives. They tell lies (white lies), they steal (successful financing), they bully (feel that others should know their place), they cringe (are careful and conservative), and they are intolerant (have a position in society to hold). Before attempting to deal with a family of this type, the physician must decide what he expects to accomplish. Obviously he can do little for the child unless he changes the attitude of the parents. Patience on his part will be more effective than coercion in helping parents to understand gradually the need to change their views and interpersonal relationships.

#### PROPHYLAXIS

*A child whose psychologic needs are met is well on the road to good mental health and a successful social adjustment.* The physician will do a real service by explaining these needs to the parents. They are as follows:

1. *A sense of belonging* in his family group, a position he has because of who he is rather than of what he does. Parents should show this attitude toward their children by word and by act. Children are quick to sense the implications of voice sounds even before they understand the meanings of words. They also require physical expression of affection throughout childhood. Parental championing is necessary as a sign to the child that he has protection and a safe haven. Parents may bestow praise or blame; nevertheless the child has an assured place that he cannot lose. Such

factors are the psychomotor tensions which mold the child's behavior patterns. The child who does not have the feeling of belonging is termed "the rejected child."

2. *A set of parents with whom to identify* while growing into manhood or womanhood from infancy through adolescence. This means a father and a mother who are around enough so that the child can see what a man and a woman are like, and how they meet life's experiences. Through imitation, but even more by unconscious identification, each child will fashion himself after his parents, one day having full recognition of his own identity as a person.

3. *Experiences in being needed*, in the sense that the family actually depends upon him for some part of its life. These experiences must be real; the child quickly sees through artificially created chores or responsibilities which a parent will take over when he fails. For example, most so-called student government plans do not fool children when they become aware that an adult will see that nothing serious will happen.

4. *Opportunities for finding satisfaction in the world about him*, rather than in his day-dreams.

5. *A chance for adjustment with a group* which will help him to be both a follower and a leader. He needs to feel the advantages of being an individual, yet a person who also is able to fit into a group.

6. *Experiences in self-sufficiency and independency.* In the first two years of life the child is naturally dependent for much of his care. However, even by the sixth month he begins to strike out for himself in self-feeding, and from that time on has a drive to take care of himself. In becoming independent he regresses, on occasion, as if to get strength before moving ahead. Parents expect independence to proceed regularly, and even rapidly. Such parents tend to force and urge independence, which may lead to greater clinging. Others try to hold back, which leads to a clash of wills as the child fights for the chance to be on his own. The physician can serve as an interpreter of the laws of behavior and as arbiter in the struggle between children and their parents.

7. *The security of stable circumstances*, particularly of dependable human relations. Children are confused and emotionally upset when parents are in disagreement. The discipline which every child craves should be consistent and understanding.

### PROBLEMS OF TRAINING

Parents and the physician must try to find out what the child is attempting to do. The child's methods need not always be approved, but certainly he is not to be laughed at or scorned. There must be honest explanation and direction; there should be praise for correct actions and as little emphasis upon wrong ones as possible. Demands must not exceed the child's ability; and the natural consequences of his acts should be pointed out, rather than an attempt made to control them too stringently.

**Obedience and Discipline.** Problems related to obedience and discipline will come to the attention of the physician. The most frequent are (1) *insistence upon obedience for its own sake*, all sorts of unreasonable acts being demanded of the child. Such important matters as musical education or the drinking of milk are frequently confused with the highly engaging but totally irrelevant question of "Who's going to win?" Problems related to authority should be anticipated; i.e., the child should clearly understand what penalties will be imposed for certain acts, and these penalties should be invoked if the acts are committed. (2) *Too much authority and punishment.* A child becomes negativistic and rebellious when parents insist upon too many rules and regulations. (3) *Irregular discipline.* When discipline is neglected, the child does as he pleases in disregard of threats of punishment, only to have the whole storm break suddenly, often over some trivial matter. (4) *Failure to realize that a child must be taught obedience.* When he is allowed to do what he pleases under the guise of unhampered development, he must learn bitter lessons later in life. When the physician advises some degree of control of a child in such a family, he probably will be looked upon as an ignorant barbarian. (5) *Divided authority.* When one parent is strict and the other lenient, each in emphasizing his or her attitude tends to counteract the other. A situation between the father and the child should be their affair, and bringing the mother into it is a sign of weakness. If she disagrees with the father, both parents are in a most embarrassing situation which the child will not forget. If she agrees with the father, the child is crushed. It is inexcusable to humiliate a child before adults or other children.

**Punishment.** Punishment should be kept to a minimum. It should be short and meaningful, and should be related in time as closely

as possible to the wrongdoing. In some instances spanking may be the only appropriate punishment, in others deprivation may be more effective, and many children are adequately disciplined merely by words. So far as possible children should know what act will incur a penalty, and the penalty which has been explained should invariably be insisted upon. Corporal punishment has fallen into disrepute because many parents use it to vent their own exasperation; but, properly administered, a spanking is much to be preferred to long and vague verbal attempts to clear the situation.

**Cruelty.** The physician will often be consulted about cruelty of the child. In most instances this is nothing more than the child's ignorance of the effects of his curiosity or overweening affection. Persistent and willful cruelty, like jealousy, is a strong indication that the child needs psychologic help.

**"Dawdling Play."** Play, often of an aimless sort, is a constant necessity in youth; but many parents who think of life only as a serious affair worry over any play that is not educational. A child appears normally to waste much time; perhaps these are the periods when he solidifies the gains made at such lightning speed at other moments.

**Negativism.** Doing the opposite of what is asked may be a defense reaction against too frequent correction. It is difficult to treat, because most parents insist on advice as to how to make the child obey, when the problem is that he has already had an overdose of precisely that. All normal children show periods of negativism as they try to adjust to growing pressures from the world around them, and the physician may well worry over the emotional retardation of the child who is uniformly compliant and polite. A "negative" child often demonstrates a physical withdrawal, a stiffening or shrinking which is the opposite of cuddling. In a group he always manages to be a little apart from other children instead of merging with them.

**Carelessness.** Parents frequently complain of carelessness and lack of cleanliness. Within limits these faults must be considered part of the average child's behavior. They are often inadequately dealt with until interest in the opposite sex occurs at adolescence, when a rapid improvement may be expected in the care of clothes and in personal appearance. In the earlier years carelessness can sometimes be overcome by removing toys or other possessions from the child who does not treat them properly. The penalty must be made

clear ahead of time; then it must invariably be carried out if the occasion arises.

## PLAY

All children like to play. Unobtrusive supervision is necessary, but play should not be interfered with. Perhaps more can be learned about a child through his play life than through any form of study; it is the time when he builds his own culture. His real venturings or timidities, his ideas as to what is fair, his sociability, and so forth, are not trammelled in play by what he thinks his parents want. The physician should know in general the ages at which the child plays peek-a-boo, tag, hop-scotch, marbles, and the like; he will then have a quick and reliable index of the child's emotional age or contention intelligence. Play with other children should be encouraged because of the great educational values of imitation, competition and the requirement for emotional control.

The most important criterion to be met by play materials is that of safety. Toys should not have sharp corners, cutting edges, exposed mechanisms in which fingers can be cut or pinched, or small detachable parts which could be swallowed or aspirated. If the eyes of dolls and animals are not fastened securely, they should be removed, and embroidered or painted eyes substituted. Toys should be colored with lead-free paint or vegetable dyes. They should be sufficiently durable to withstand banging, dropping and general abuse. Washable toys are preferable, particularly for young children. The child's toys and games should be appropriate to his stage of development. Children two to four years of age prefer simple and realistic toys rather than too many or too elaborate ones. Older children should be supplied toys or play materials with more detail, which allow individual effort and skill to be exercised. Large but lightweight blocks which demand arm movement should precede the smaller ones with which the fingers must be used; these small blocks in turn must precede large crayons or chalk, and these again must be used before small crayons and pencils. Each child is his own competent guide as to when certain reflex arcs are ready for use; he will invariably use the finer adjustments of the muscles at the ends of his arms and legs when the mechanisms for them are ready. Hastening of writing and of using intricate toys should not be permitted.

## SEX EDUCATION

Curiosity about the anatomic and physiologic differences between the sexes always arises in the child's mind, and information must be furnished from some source. This curiosity is at first only part of the child's general inquisitiveness. A child who does not ask his parents questions about sex either is being instructed elsewhere, often incorrectly and viciously, or has been repulsed. When the physician is consulted about the child's persistent interest in sex, he will find that this interest comes mainly from the parents' own disturbance over such questions. Obscene pictures and notes, which bother teachers so much, almost never originate from children properly placed in school and happy in their work. The child uses discussion of sex to gain certain important ends. If the physician cannot spare the time to find out what the child is trying to do with his so-called sexual interest, he had better let the matter alone. Treating the problem as a sexual one only assures the child that his methods are efficient. There are infrequent exceptions to this rule; some of these originate in abnormalities or irritative conditions of the genitals, others from maladjusted playmates.

The natural educators in matters of sex are the child's parents, who have the opportunity to answer naturally the normal and simple questions as they arise. Few parents, however, or even physicians are able to answer such questions without embarrassment. The present-day insistence that parents tell the truth has created a difficult problem for most of them. Adults do not even have a good vocabulary for this sort of venture. Parents should tell the truth, if they know it, and can tell it without having the child realize he has asked an upsetting question. If not, they had better resurrect the story of the stork, rather than let the child feel that there is something sinful and dirty about his questions. It is far more important that the child come to adolescence with the right attitude about sex than that he have stray bits of information which he has to learn over again.

In young children discussion of methods of reproduction in plants and lower animals leads naturally to the same questions concerning human beings. The presence of dogs or other animals in the neighborhood helps the child to realize the naturalness of the reproductive cycle. The mother can usually act better as an instructor for older girls and the

father for boys, although with younger children of both sexes the mother more naturally meets the issue. If parents are unable to supply adequate sex education—and many cannot—it is better, for children past eight or nine years of age, that someone such as the physician take the time to do this simply and naturally. Explanation should be given to the boy at the proper age when he must expect certain physiologic changes such as erections and nocturnal emissions; the girls must likewise know the facts of menstruation and their significance.

There is a surprising amount of homosexuality at the age of puberty. This takes the form of "crushes" between girls; and the same phenomenon occurs, although less markedly, in boys. The harmfulness of these usually temporary homosexual tendencies is greatly overestimated. The treatment must be indirect by seeing that there is healthy play life and satisfactory school adjustment, by discussion of budding plans for the future, rather than by direct attack upon the wrongness of

the affair. Masturbation is discussed on page 79.

# PSYCHOLOGIC DISORDERS

## GENERAL CONSIDERATIONS

Deviant behavior in infancy and childhood usually results from a clash between the biologic drives within the child and forces outside of him. These outside forces may be parental or other environmental influences which for the most part serve as useful agents in the acculturation of the human organism so that he will one day fit into society; unfortunately, attempts at acculturation are often made prematurely and inappropriately. The pediatrician has a responsibility in protecting infants and children from such trauma. To do this and to promote optimal development and maturation, he must understand the needs of children, patterns of growth and development (physical, psychologic, social and intellectual) and the dynamics of behavior and of interpersonal relationships. This also implies an understanding of the role of parents and of their rights in parenthood. It is an old saying in pediatric practice that "treatment of a child includes treatment of the mother." A child is cared for best when considered in the environment in which he lives and grows.

Many of the behavior problems for which children are brought to the pediatrician, such as "nervousness," temper tantrums, finger-sucking, eating and sleeping disorders, turn out on investigation to be normal responses of infancy and childhood. At times they may be exaggerations of normal traits. They are problems when they cause concern to parents and others in the community, although the behavior itself may not represent abnormality in the child. Presentation of a problem in such instances may be indicative of psychologic disturbance in the parent. The remedy will then be more in helping the parent than in treating the child.

In children over five years of age behavior problems and emotional disturbances usually signify psychopathology within the child, even though the causes may be in his environment. After five years the psychologic mechanisms within the child are activated in a

more complex fashion and produce behavior which tends to be less infantile and to resemble some adult responses to psychologic difficulty. With growth and maturation of the child, behavioral reactions assume patterns in keeping with his developmental status and his cultural milieu. As a result it is common for children over five years of age to present (1) psychosomatic illness (pain, constipation, diarrhea, colitis), (2) neurotic symptoms (tension states, anxiety, fears, compulsions, tics, hysteria) which resemble the neuroses of adults, (3) conduct disorders, (4) sexual aberrations, and even (5) psychoses.

It will be helpful to the pediatrician if he is able to view child development in the following way: The child is a product, first, of his ancestry and, second, of an interaction between himself and various forces. These forces consist of physical, psychologic, cultural, social and economic forces in his environment. For example, the physical factors include pathogenic organisms, thermal and chemical elements; the psychologic forces contain influences of family members, of playmates, of teachers and physicians and nurses who take care of the child. The cultural forces consist of the current community attitudes toward child care and child rearing, including taboos, folklore and misinformation. Behavior and emotional responses which result from the interaction of the individual and the various influences of the community will be considered normal or abnormal by various standards.

The pediatrician may be called on to distinguish the usual from the unusual in behavior patterns, which is not always easy. Some emotional responses such as fear are natural to a child when he faces real danger, but exaggerated fear of a situation not fraught with danger is abnormal and may have its roots in a number of causes. In general, proof of the normality of many behavior reactions is that all children react more or less with such behavior when confronted with similar situations. When a behavior pattern which seems

extreme persists and is demonstrated by the child repeatedly under situations of ordinary stress, and in time is joined by other symptoms of dysfunction, it may be said to be psychopathologic. It is helpful in determining whether an emotional reaction is normal to consider the stage of psychologic development of the child and to appraise the environmental situations in which he is attempting to adjust. From these and from his life history one may estimate the progress he is making toward a healthy adult emotional development.

#### PSYCHOTHERAPY IN PEDIATRIC PRACTICE

The methods of study and treatment of children with psychologic disorders are, in general, the traditional ones of history taking and examination, but with insight learned from modern psychology. Diagnostic study and therapy proceed together; treatment begins with the very first contact between parent, child and physician.

History taking accomplishes two purposes: (1) collection of data, and (2) therapeutics. The medical history should be an anamnestic interview which does more than record the history of disease or somatic development. It should be the historical account of a human being who comes or is brought to the physician for help because someone feels concern. It is natural for the person coming for help to begin with a statement of the chief complaint, presenting symptoms and reasons for seeking assistance. The complaint is frequently on a somatic level and may include a list of behavior characteristics which disturb the parents more than the child. The first complaint uttered may not be the chief reason for coming to the physician, but, instead, may be a disguise assumed consciously or unconsciously to make a favorable and acceptable impression.

In order to understand the origin and development of the complaint in its relation to the current situation, the informant (usually the parent, but sometimes the child) must have ample time to tell the history as he sees fit. The life history may not be given sequentially; it will be reviewed best when the informant feels free to talk spontaneously without feeling the need to follow a rigid pattern. In such a setting the informant is often able within a unit of time set by the physician, or in a series of interviews arranged closely together, to talk frankly about his difficulties.

As the history is told it usually becomes evident, often even to the informant, that the onset of the symptoms or disturbing behavior coincides with periods of particular stress or disturbing contemporary events. The account of the present illness also often makes it clear that contemporary difficulties have their precursors in the earlier life of the patient. The difficulties may even be repetitions of earlier patterns of adjustment and maladjustment. The medical history provides data about the family at the time of the pregnancy and birth, the feelings of the parents toward each other and toward the newborn baby, about birth, early feeding and sleeping and many other details. *However important such data are, there is still greater significance in gaining, through the medical history, understanding of the feelings and attitudes of the parents as they care for the child in everyday matters such as feeding, toilet training, education and discipline, and of the infant's reactive feelings to these measures.*

The pediatrician who conducts the interview in this way soon recognizes that a relationship has been set up between himself and the patient. The informant quite as much as the physician recognizes that something helpful is taking place as he spontaneously presents material about himself and his family in a longitudinal and associative perspective. This interpersonal relationship, which may be called rapport or transference, is essential for therapy of any kind, whether medical, surgical or psychiatric.

The "talking-out" treatment, to be fully effective, must contain two basic elements: (1) the person must feel free to talk to an authoritative person such as a physician, and (2) the physician must be interested and sympathetic, able to listen and not bound to do something hurriedly. When he talks, he should use carefully chosen and properly timed questions and note whether the responses bring relief or upset the informant. He will be guided in how far to go and what topics to discuss by these responses. Under no circumstances is his task that of probing into conscious or unconscious motivations, exacting confessions or judging critically. Instead, he should attempt to develop confidence so that the informant will naturally bring out memories of the past and knowledge of the present which are relevant to the problem.

Such sharing through talking is beneficial and, when accompanied by simple explanations of the mechanisms involved in the etiol-

ogy of symptoms, may lead to a better understanding by parents of themselves and of their children, and of their mutual problems. One such psychologic adjunct is reassurance, and in this the authoritativeness of the physician may be used in a healthy manner. A physical examination done carefully is, in itself, reassuring, not only when no disease is found, but even when dysfunction is revealed. This kind of reassurance is truly therapeutic and quite different from that of the back-slapping and "cheer up" variety. The physician who has confidence in his ability to examine a child and to appraise the results conveys this feeling to the child and his parents.

Should the physician, for the sake of scientific completeness, subject the patient to po-

tentially traumatic examinations unnecessarily, he may cause severe emotional trauma. This point is particularly apt in the treatment of such conditions as enuresis, in which unnecessary instrumentation of the genitourinary tract may accentuate rather than help the basic problem.

The pediatrician as a psychotherapist may need assistance, and the psychiatrist as a consultant may be of help both to the pediatrician and to the patient. Social workers are trained in understanding individual, family and community problems, and their services may also be utilized in the therapeutic regimen. Psychologists constitute another group of skilled workers who can assist in therapy through performing tests of intelligence, aptitude and personality.

## NEUROTIC TRAITS

Psychologic dysfunction is often more readily recognized in adults than in children. Although classification of psychologic disturbances is usually not clear-cut and final, it is customary to consider deviant behavior of adults as neurotic, psychotic or psychopathic. In children it is difficult to distinguish between a neurosis and normal behavior; differentiation of a psychosis from a neurosis may be equally hard; and the term "psychopathic" is rarely used. The child responding to everyday stress in the home, at school and in play normally exhibits behavior which resembles neurotic or psychotic behavior of adults.

### "NERVOUSNESS"

In the strict sense, nervousness should not be considered a diagnostic term. At best it represents a symptom-complex and is here applied to children who are abnormally and persistently *restless*, both physically and mentally, who *fatigue easily* and have a *short span of attention*, and who are *overexcitable or timid* without apparent physical cause. The term is much abused. Many parents speak of children as being nervous as an excuse for any sort of fault in upbringing; many physicians use the term to cover their ignorance of the underlying difficulty, and other physicians use it as a means of getting parents to ease the pressure being exerted on the child. The fact remains that many children are

brought to the physician because of "nervousness," and even after the closest scrutiny some remain in this category. For this group of children some designation is necessary.

Some children are congenitally overactive. They have a heightened sensitivity to all sorts of stimuli. Any sort of trauma will produce essentially the same picture, which will disappear with clearing of the disturbance. Continued heavy loads and stresses may produce nervousness, as may severe acute illnesses.

Children also acquire nervous habits by association. When the family is a tense, keyed-up group, even the most placid child will exhibit classic symptoms. Nervous people can live happy, well-adjusted lives if they will accept themselves as such and are so accepted by others. For those who are not inherently nervous, the cause must be detected and eradicated.

The loads which may result in nervousness include the following: (1) undue adult pressure for accomplishment; (2) too much stimulation in play with older children; (3) competition for school promotion or high grades; (4) physical and social inferiorities, such as belonging to a minority group or having fewer advantages than their neighbors; and (5) anxiety reflected from parental worries and from other causes.

Anxiety is a basic emotion with which the growing child and adult need to contend each day. If the physician is able to protect

children from some of the excessive loads our culture often forces on them, they may be happier and healthier and able to achieve better performance levels in the home, in school and in society.

**Clinical Manifestations.** The nervous system seems unable to withstand the strain put upon it, so that the child is restless. The inhibitory powers are decreased, so that there are exaggerated responses such as "flying off the handle" with mild teasing or with frustration. There is usually a sort of tenseness; the pulse and breathing rate rise as the physician approaches, and the muscular movements are quick and jerky. Further information may often be secured by having the child "draw pictures." The nervous child does not make flowing, easy lines and, in his effort at control, often draws minute, exact, short lines, grasping the pencil with firm grimness. The physician will recognize the tightened voice and the inability of the child to be at ease as he sits in the office. The reaction time is usually speeded up, and the responses are inaccurate, as though there were a hair-trigger mechanism that set off the gun before there had been careful aim.

With these basic symptoms there is likely to be every conceivable sort of superficial disturbance which tends to be manifest in the higher reflexes. Thus stammering, reading and writing difficulties, finical appetite, nausea, and clumsiness in fine hand work may appear. The child does not go to sleep easily and shows tenseness in his sleep. Vegetative disturbances include sudden flushing, irregular heart rhythm, and fluctuation between constipation and diarrheal stools.

**Prognosis.** This depends upon the cause. Some children are "coiled up watch springs" and will always be so, but they can make excellent adjustments if this fact is recognized. They should be kept from long, repetitive tasks. Thus they negotiate the school regimen, provided they are given extra outlets for their pent-up restlessness, such as errands two or three times during the day or more black-board work than the others. They are usually happier in high school where they move at the end of each class period. Parents can help by avoiding pressures at home.

But most nervous children are so because of some intercurrent factor such as illness, or extra loads. In such instances the prognosis depends upon how effectively the exciting factor can be eliminated.

**Treatment.** The management of the nervous child is frequently within the province of

the child's physician, the psychiatrist being needed only in the unusual case. The principles set forth in the discussion of mental hygiene (p. 67) should be followed as prophylactic measures. The frequency of maladjustment to environment must be recognized and the situation dealt with accordingly. Late hours, broken sleep, excitement of the young infant by visitors, and other disturbing causes should be avoided; later, caution must be used against forcing him into precocity by efforts to teach him to talk or walk or to advance in mental and physical development beyond what should be expected for his age. In infancy and after there must be an abundance of mental and bodily rest. Especially in the school years careful supervision and judgment are required. A middle ground must be chosen between too much and too little study. Parents must be careful not to be coaxed into yielding to each whim, preparing special foods and constantly exhibiting anxiety. The physician should not discuss the child's problems in his presence.

Tasks and projects should be of a duration in keeping with the child's physical and psychologic condition; sometimes short-time projects are less productive of tension and hence lead to greater accomplishment. If the parents have wisdom, they can appreciate that they must strike a balance between a strait-jacket routine and no routine at all. The "nervous child" realizes that he needs support and welcomes a reasonably planned routine that relieves him of this responsibility.

If the parents lack the required wisdom, it may be advisable to remove the child from some of the unfavorable influence of home associations. Often nursery schools will afford help in these situations. This brings up the subject of parental, substitute parent and group care. Mothers should understand that the young child, up to three years of age as a rule, derives his greatest security from a sense of belonging intimately to his parents. In general, during the first few years of the child's life, parents (particularly the mother) should be discouraged from relinquishing their roles to other persons except for short periods and for emergencies, and then only if a responsible and understanding adult is chosen. First-rate nursery schools with a sufficient number of well trained teachers may serve the child under three years in this way, but as a rule they function best with children over that age, supplementing the child's life where it is needed most in play, companionship with peers and in relationships with understanding

adults. Summer camps, except those which have too strenuous routines and those which are entirely devoid of organization, may be utilized for the vacation months for the school-age child.

Every effort should be made to improve the general health of the child. The diet should be abundant and contain all the necessary minerals and vitamins. After any acute illness there should be an adequate convalescent period. Encouragement and efforts to increase the child's self-confidence are of the utmost importance. Nothing can be accomplished by compulsion, scolding or ridicule when undue fears are present. The nervous child who has a fear of sleeping in the dark should be allowed a dim light in his room until the fear is overcome. With older children a quiet and sympathetic discussion of their fears and an explanation of the groundlessness of them may be helpful; with infants pleasant sensations may be gradually associated with the cause of fear, if the source cannot be removed. Disciplining of nervous children is, of course, required on occasion, but should be adjusted to the child as well as to the offense, and those forms chosen which will not awaken fright or increase anxiety. These children often are afraid of what they might do, and they welcome discipline as a sign that someone else is "keeping them from going too far." There should be *just enough* of this authoritative control.

Sedatives may be required on occasion, but ideally should be given only if the physician is sure that he has located the cause and is well on the road to its removal. At such times sedatives can act to break a pattern that has become self-perpetuating.

### THUMB-SUCKING

Besides thumb-sucking there may be sucking of the tongue, fingers, toes, lips or such objects as a rubber nipple or "comforter," a blanket or sheet or part of the clothing. Much of this is common in infancy, since by this pathway the child explores his world, and it is a matter of little significance in the early months. The sucking may be accompanied by other acts, such as rubbing at the nose, pulling at the hair. Parents have often read enough literature to have become confused, and the physician will find that the main part of treatment is the difficult task of allaying adult anxiety. Thumb-sucking is more likely to occur when the child is about to go to sleep or when he is hungry, sleepless

or ill. It may become a persistent matter when the child feels put out of place by other arrivals or by some other matter absorbing the parents' interest. In these latter instances the physician obviously cannot treat the sucking habit directly, since it will disappear only as the child feels firm in the family affections. In milder cases when sucking is only occasionally practiced, the child may be easily diverted from it. When thumb-sucking is continuous and intense, temporary or, rarely, permanent malposition of the teeth may result, but seldom if ever of the palate; permanent alterations of the thumb rarely occur. The duration of the habit is indefinite; most infants cease of their own accord, but it may last into childhood.

**Treatment.** In mild cases treatment is unnecessary except for reassurance to the parents, which at times may be difficult. When hunger is the initiating factor, cure results when the diet is made sufficient. There is also evidence to suggest that the length of eating and sucking time should be increased, since the sucking habit often results from the fact that rapid eating satisfies the hunger reflexes before the lip and mouth reflexes have run their course. Mechanical restraints, such as elbow splints, metal mitts or thumb covers, are to be avoided. Their use is liable to aggravate rather than help the situation, especially the emotional aspect of it.

### NAIL-BITING

#### (ONYCHOPHAGY)

Nail-biting is common and in sensitive children is related to tension, excitement and worry. Both the causes and the treatment are much the same as for thumb-sucking. It helps to keep the nails cut short, and the fingers may be protected by gloves, though this is likely to allay the feelings of the parents more than it helps the child. All direct approaches must be in terms of pride in nice nails rather than shame for the habit. If possible, the underlying difficulties should be corrected. In all instances nagging and scolding should be avoided and efforts directed to increase the child's self-confidence and sense of security in the home situation.

### TEETH-GRINDING

Teeth-grinding is observed chiefly during sleep; it may be associated with various acute and chronic disturbances or may be indicative merely of mildly disturbing dreams. It

is common in unconscious states which are dependent upon disease, especially of intracranial origin, and it is a frequent symptom of meningitis. It is not pathognomonic of intestinal parasites. It may occur during the waking hours in low grade feeble-minded children, as may any of the neurotic habits. Treatment of teeth-grinding, if any, must be directed against the cause.

### PICKING, PULLING, AND RUBBING HABITS

Picking, pulling or rubbing some part of the body may develop as a habit. Fatigue and emotional stress are to be looked for, as are also disorders of general nutrition. Actual local irritation may be involved. Children suffering from severe illness of any sort often pick at the lips so continuously that restraint is necessary. Fretful infants frequently pull at the hair (*trichotillomania*), and large areas of the scalp may be almost denuded. Continuous eating of hair leads to the condition of hairball in the stomach. A frequent and annoying habit is that of picking at or boring into the nose, for which there is sometimes a local irritating cause.

**Treatment.** Forcible restraint may be necessary in infancy, but should be used only for severe disturbances; in older children reward for ceasing the habit is better than too much admonition, and restraint is seldom indicated. It is important to improve the general health and to remove any local irritation. Frequently these habits are manifestations of unhappiness, and shaming the child only increases the problem even when it temporarily seems successful.

### RHYTHMIC MOVEMENTS

Rhythmic movements occur frequently in mentally defective children, occasionally in infants and children who are emotionally disturbed and at times even in those who are apparently normal. The movements may be of one or more varieties.

**Head-Banging.** Head-banging is a rhythmic knocking of the head against the bed or mattress. This practice is not uncommon among infants and young children, and may occur in those of normal mentality as well as in mentally deficient ones. The habit is usually practiced shortly after the infant or child has been placed in bed, but may be carried out even during sleep. The child rarely injures himself. The habit is usually terminated between the second and fourth years of life.

No treatment is indicated other than removing sharp objects from the bed.

**Head-Rolling.** Head-rolling is not uncommon under the same conditions as head banging, but is more likely to be seen in undernourished or chronically ill children. The child, lying in bed, rolls his head from side to side, and continues this procedure day after day. As a result, the hair is almost completely worn away from the back of the head.

**Head-Nodding.** Head-nodding is to be distinguished from the gyrospasm and nodding spasm described on page 1102 in that it is much more energetic and apparently intentional. It occurs while the child is sitting, and it may be either a vigorous nodding or a lateral shaking movement.

**Swaying, or Body-Rocking.** This is a common habit. The child in a sitting position rocks rapidly backward and forward and continues this movement for hours, generally without the evidence of excitement usually seen in masturbation. Treatment consists in improving the general health and in combating, if possible, any psychologic difficulty present, but not in forcible restraint (see Sleep Disorders).

### BREATH-HOLDING

Holding the breath cannot strictly be called a bad habit, although it is sometimes seemingly voluntary. It is due to emotions like anger or to excitement. It is seen in irritable and high-strung infants and small children who cannot restrain their emotions. Attacks begin most often in the latter part of the first year of life, and generally disappear by the age of four or five years.

When something displeases or startles him, the child cries and hyperventilates; this causes a sudden cessation of respiration, followed by cyanosis and rigidity. In severe cases there is momentary loss of consciousness (syncope), possibly convulsive twitching (p. 1127), pallor which is sometimes extreme, and finally general relaxation. In a few seconds the attack is over and the patient appears as well as before. There may be recurrences several times a day or at longer intervals. In some instances the attack constitutes the terminal stage of a fit of rage, in which the child throws himself on the floor and screams violently for a few moments, or the attack may be both preceded and followed by crying.

**Treatment.** The child should be ignored during the attack, but measures should be

taken to remove precipitating conditions and to correct any faults of general health or environment. The question of discipline depends upon the individual case; punishment itself may cause an attack. Kindness and understanding are more effective than harshness in combating the neurotic condition.

## MASTURBATION

Masturbation is a common habit, and seldom of serious consequence. Impairment of the general health may predispose to masturbation or cause its renewal. Local irritation is a factor in many instances, such as phimosis, the accumulation of smegma behind the corona, balanoposthitis, irritation from tight underclothing, vulvovaginitis, the itching produced by eczema or by the presence of threadworms in the rectum or vagina, constipation, highly acid urine, preputial adhesions and adhesions of the clitoris. Sometimes irresponsible nurses have habitually rubbed the penis of an infant for the purpose of soothing him. In older children masturbation may be initiated by the sensation created by sliding down a banister rail, climbing trees, horseback riding or tight clothing; but at this age it is often taught by companions. At this period of life it is more frequently practiced by boys, although as puberty is approached or even before this time the habit is frequent in girls as well.

**Clinical Manifestations.** In infancy, masturbation usually consists in thigh friction or associated movements. The infant, sitting on the floor or lying on his back with the lower extremities drawn upward, rubs the thighs vigorously together, thus catching and rubbing the genitals between them. The face meanwhile becomes flushed, and the eyes have a fixed, somewhat staring expression. After a short time something suggesting an orgasm is produced, sweat breaking out on the forehead, the face growing paler, and the infant lying back relaxed from temporary exhaustion. The procedure is repeated possibly many times a day or even during sleep. Infants who practice thigh friction may exhibit other signs of neurotic excitement. Examination will frequently show redness of the genitals and perhaps some local source of irritation. Various modifications or substitutions of typical thigh friction are seen. Some infants, lying on the back or sitting, rub the buttocks from side to side on the bed or floor; others rub the genitals against some object, such as a pillow or the leg of a chair. Some-

times movements of other parts of the body are associated with, or even appear to take the place of, those which directly cause friction of the genitals.

After infancy, masturbation is more clearly associated with an early development of sexual excitability. The hand is generally used, and thigh friction is uncommon. As the result of reproof and consequent consciousness of wrongdoing, the habit soon becomes a secret one. Generally the procedure is only occasionally performed, but in extreme cases, when the child is highly neurotic, he may lie awake at night masturbating, or he may perform the act in the day; sometimes he may lose all sense of shame and power of self-control and masturbate in public as well. The local manifestations are varied. The penis may be unusually turgid or enlarged, with a tendency to ready erection, or it may seem relaxed. However, spontaneous erections are frequent in children who are not masturbators. The prepuce may be swollen and slightly inflamed. In girls the clitoris and labia may be larger than normal, and there may be some degree of vaginitis. These signs, however, may all be absent. Excitability, nervousness, apathy, depression, morbidness, shyness, reticence, pallor, loss of memory, debility, headache and many similar conditions have often been ascribed to masturbation; but they are likely manifestations of a neurotic state responsible for the habit. Likewise feeble-mindedness or some psychic disturbance is the cause of masturbation rather than its sequel. Nevertheless frequent masturbation may have an exhausting effect upon the nervous system; and the consciousness of concealed wrongdoing is emotionally disturbing.

In the analysis of a particular situation the following factors should be considered: (1) For children up to five or six years of age there is a tendency on the part of parents to overemphasize masturbation. At any time when the hands are in the genital area, there is much forbidding and shaming, which results in emotional strengthening of the habit. In such instances masturbation can be controlled only when the family really accepts the physician's reassurance that no harm will eventuate, and then only as he convinces them that the child cannot give up the habit until they cease to make it the center of their interests. (2) From about six years on masturbation—like smoking or wearing long trousers—is often a symbol to the child that he does things older people do. There is

therefore a great deal of experimenting as a perfectly normal phenomenon of growth. Adult admonition serves only to impress the child that he is trespassing on adult premises, so that the act attains even greater symbolic value. There is no evidence that harm results, unless the parents or physician has succeeded in loading the habit with so much guilt that the child develops a sense of inferiority. The ready and intense emotional satisfaction that comes from the production of an orgasm must be recognized as a factor favoring continuance of the habit. Masturbation offers a constant invitation to those who are failing in social or scholastic fields. It is important that the child have satisfying outlets in social activities.

**Prognosis.** Thigh friction or other forms of masturbation in infancy usually cease as early childhood is approached, except when masturbation is frequent and a distinct pathologic psychic condition is present. In early childhood there is a tendency to discontinue the habit; in older children it readily becomes fixed. The prognosis, however, for the general development of the child is good, except when masturbation is excessive. Here it is frequently an evidence of severe neurotic disturbance.

**Treatment.** In patients of any age, search must be made for local causes of irritation, and they should be removed. Vulvovaginitis, if present, demands treatment, as do threadworms, constipation and eczema.

Further treatment in older children is frequently unsatisfactory. As a prophylactic measure, proper instruction should have been given in sex matters (p. 71). The general health may need attention, and nervous excitement should be avoided. Life in the open air with abundance of exercise is important. However, abundant and healthy outdoor activity may increase the sexual appetite rather than drain it off. Erotic literature and movies should be guarded against. Punishment is of little value and only makes the patient more secretive. Emphasizing the practice as a sin may cause only despair and even cessation of efforts at control when good resolutions are broken. The confidence of the child should be obtained and the problem presented as a universal one. There should be frank admission that there are no known bad physical effects, but that it is difficult to escape disturbing feelings of guilt and unworthiness from the practice. The activities of the child should be planned so that there is a minimum of opportunity for the practice, but without

the child's being aware of such control. Surveillance which is too apparent serves only to concentrate the attention of the patient upon his practices and to establish the habit more firmly.

## COMPULSIONS

Compulsive acts are responses to thoughts which come obsessively. As a rule, compulsive behavior does not appear before the age of five or six years, and is so frequent after that time that it may be considered normal until the age of puberty. Although such behavior may on occasion be excessive in children under ten to fourteen years, if prolonged beyond this time it is usually considered symptomatic of psychopathology. A compulsion represents a reaction to the child's conscience, which around five years becomes excessively stern, even though the outside pressures may not be unusually hostile. In this period of development the child's feelings of hostility toward people close to him seem unbearable; the child may feel guilty about this, even though he does not recognize what he feels guilty about. Unconsciously he will repress some of these feelings of hostility and will take on behavior which seems to ease his conscience. Although this behavior may be unpleasant and therefore be resisted in part, the child will continue to act in this manner as if to avoid anxiety. Compulsions represent a kind of penance. Such behavior is incongruously proper, careful and repetitive. For example, the child may feel the need of touching certain objects, of counting or repeating numbers or words whenever a certain occasion presents itself. It is common to find the practice of walking so that cracks in a sidewalk are not touched. At times there may be compulsiveness about cleanliness which seems related to the child's early training in toilet habits. He may avoid defecation, so that severe constipation results. (See Constipation, p. 652.) The child of five years and older is especially prone to consider thoughts of sex and genital function as wicked, and his conscience seems to be especially strict about these matters. When parents are unusually stern, such thoughts of the child are exaggerated.

Ordinarily, mild compulsions disappear as the child works through the stages of prepuberal and puberal development, and no treatment is indicated. At any age, however, when compulsions occupy much time or incapacitate the patient to any degree—for ex-

ample, in excessive hand washing, chronic constipation (psychogenic), precautions against germs, elaborate ceremonies in eating, dressing or going to the bathroom—and especially if they are accompanied by other evidences of tension, worry or social withdrawal, psychiatric treatment should be sought.

## ANXIETY AND FEAR

Fear is a normal human reaction; all children experience fear in some degree from birth. The newborn is alarmed by loud noises and loss of support. Fear serves a useful function in protecting one from physical danger and in developing traits of caution and discretion. When fear is absent, one may question the mental status of the person, inasmuch as he is incapable of protecting himself and probably others in the community. Often fear becomes attached to objects and situations in an excessive way. Many infants about six months of age show fear when approached by strangers. Up to that time they may have accepted every newcomer willingly. As the infant grows he learns to rely more on his mother, and he feels apprehensive when she is not around.

Parents may foster fear by either insisting that the child be separated from them and become independent before he is ready for it or, on the other hand, by assuming an excessively protective attitude, preventing the development of independence. The child between one and a half and three years of age is in a phase of development in which he wants and seeks increased independence, but at the same time there is also an increased dependence. This ambivalent attitude causes many clashes between parent and child. The child demands that he do things himself and without help, yet he also demands help from the mother as well as her presence during each day.

As the child grows older he has many fears which are now verbally expressed. For example, a child at three and four years of age may show a fear of animals out of all proportion to his experiences with them. Nocturnal fears and nightmares are also frequent between three and six years of age. There may be an unconscious mechanism whereby fears which have arisen from daytime experience appear at night in sleep.

It is unfortunate that some people use fear to discipline a child. Parents may thoughtlessly handicap a child by telling him untruths about ghosts, bogey men and doc-

tors, or by subjecting him to frightening experiences. For example, a parent may deliberately burn the fingers of a child to teach him the danger of fire. Even less drastic handling as persistent scolding, disapproval and excessive blame may produce chronic timidity and fear so that the child develops into an inadequate and insecure person. It is remarkable how much psychologic trauma a child can take without serious or permanent injury. However, children should not be needlessly exposed to situations which engender irrational fear.

Whatever the causes of fear, children are able to handle it best when they feel secure in their relationship with their parents. Acceptance of the child as he is at each phase of his development is essential. This entails patient management of such situations as feeding, sleeping and toilet training by the parent without giving vent to feelings of rage or hostility. Many of the fears connected with sex and genital function appear to be related to early experiences in poorly devised toilet training.

Illogical or exaggerated fears are sometimes called *phobias*. Many times the child recognizes these feelings as unwarranted and unreasonable, yet seems helpless to overcome them. Sometimes a person may be so overcome by acute fear or the accumulation of it that he loses control of his behavior. The result may be severe impairment of physical and intellectual functioning. Such reaction is referred to as panic. Although clinically one may not distinguish between fear and anxiety, academically it has become customary to think of anxiety as being more malignant and irrational than fear. Anxiety is thought to result from a conflict which is repressed in the unconscious. Anxiety attacks are often characterized by somatic symptoms (p. 87).

**Prevention and Treatment of Fears.** Children become liable to certain fears at different ages which are by-products of various stages of emotional development. Children should be protected as much as possible from unnecessary and unduly fearful situations, but oversolicitous attitudes may foster fear which goes beyond the protection intended. When undesirable fears develop, they should be considered with sympathy and understanding and not with ridicule. A child should be encouraged to talk out his fears in the daytime; when nightmares occur, he should be awakened from his sleep and permitted to verbalize their content. In play he should always be permitted to act out his feelings. This is especially valuable when the child has

had an unfortunate experience through physical illness or hospitalization. Such children should talk about these events, and in play should be encouraged to set up lifelike situations in which they can act out their emotions. Irrational fears, especially if they are of long standing and assume the form of chronic anxiety, are difficult to modify and require psychiatric treatment.

## HYSTERIA

For reasons unknown, the incidence of hysteria has decreased in recent years. Rare in childhood, most cases occur in the puberal age period, more commonly among girls than among boys. The symptoms are quite varied and represent conversions of repressed ideas, wishes and intolerable emotional states into somatic manifestations or episodic behavior. Often the symptoms simulate organic disease, but are distinct in that they usually conform to the child's concept of the disease rather than to those of the disease itself. The manifestations may come on suddenly and disappear rapidly; they may simulate disease of any part of the body. Commonly there is only a single symptom. Sensory symptoms are varied, and include neuralgic pain with contracture about the joints and widespread or localized anesthesia, hyperesthesia, paresthesia, and the like. Sensory disturbances do not follow the course of nerves as would organic lesions, and are further characterized by their variability from time to time and by the susceptibility to suggestion.

Among *motor* symptoms are spasms, either tonic or clonic, and occasionally hysterical convulsions and catalepsy. The spasm may be choreiform or may be represented by contortions of the face, irregular action of the diaphragm and other muscles of respiration, and contraction of muscles elsewhere. Pseudoparalyses are much less common in children than in adults. Aphonia may occur from pseudoparalysis of the muscles of the larynx. The tendon reflexes are usually active, never absent. Cutaneous reflexes are variable, those of the cornea and pharynx being absent at times. Ankle clonus does not occur. Tremor is uncommon.

*Psychic* symptoms include attacks of laughing or crying without sufficient cause, paroxysms of violent anger, great excitability, night terrors or somnambulism, aphasia, a stupor-like condition, and states which resemble delirium and hallucinations.

Symptoms referable to the *special senses*

include blindness, contraction of the visual field, asthenopia, blepharospasm with closure of both eyes, paralysis of ocular muscles, and deafness.

There may be such *respiratory* symptoms as sighing, rapid respirations, yawning, hysterical cough, attacks of dyspnea, and hiccup from spasmodic action of the diaphragm. Among *circulatory* symptoms are palpitation, tachycardia, pallor, flushing and edema. *Gastrointestinal* symptoms may include hysterical dysphagia, gastralgia, umbilical colic, and vomiting which is often persistent. Anorexia nervosa may be a hysterical disturbance. Among other symptoms connected with the intestinal tract are meteorism, long-continued diarrhea, constipation, incontinence of feces and recurrent anal prolapse. Among *genitourinary* symptoms are frequency of urination, polyuria, ischuria and vesical paralysis.

**Diagnosis.** Although organic disorders may be closely simulated, certain features will aid in distinguishing hysterical manifestations. Primarily there is a lack of proportion between the assigned cause and the symptoms produced, and also a tendency for all symptoms to become worse when much attention is paid to them. In hysteria the patient is "gaining an end," although the purpose is often difficult to fathom, since the psychological mechanisms are often unconscious. The symptoms serve to hold the parental affections or to escape some unpleasant situation such as the greater ability or attraction of a sibling. Furthermore, there is likely to be a grouping of symptoms which it is impossible to attribute to any known lesion or lesions. It should, of course, be recognized that hysteria and organic lesions may occur simultaneously.

**Prognosis.** Active manifestations of hysteria usually improve under proper management. However, in a child of a distinctly neurotic tendency the manifestations are likely to recur. Suddenly developing attacks offer the best prognosis.

**Treatment.** Prophylactic aspects are discussed under Nervousness (p. 75). Psychiatric study and treatment are indicated in every case.

## Tics

### (HABIT SPASMS)

Tics are spasmodic, irregular movements of isolated groups of muscles. There is no direct association with organic disease. Tics occur most often in late childhood, but occur even

in the preschool age. Often a local factor determines the site of the tic, such as chronic infection of the upper respiratory tract, defective vision or irritative clothing. Occasionally imitation is the initiating factor, but more often a tic is associated with emotional disturbance. Tics occur in children of all levels of intelligence, but somewhat more frequently in those below average. Maladjustments at home or at school are common, and it is often found that pressure is being made to stimulate the child to mental or physical activity beyond his capabilities.

Tics are of various types and degrees of severity. The movements are only occasional at first, but soon tend to become frequent. They are performed unconsciously, although the child is able to restrain them for a time by force of will. They are increased in intensity and frequency by excitement. The majority of these movements are limited to the face and consist in twitching or distortion of the mouth, wrinkling of the forehead, elevation of the eyebrows, forcible winking, and the like; or there may be sighing or sniffing or jerking movements of the head. Less often there are jerking movements of the body which may be localized in the hands, arms or shoulders. The duration of the tic is variable; sometimes it lasts but a few months, whereas it may continue for years. Occasionally a tic in one region is replaced by a tic in another area.

**Treatment.** Treatment should be directed toward adjustment of the child's psychologic difficulties rather than at the tic itself. This obviously requires a careful psychologic evaluation even when the child seems to be well adjusted. Attention of the child should not be drawn to the tic or suggestions made that he attempt to control it. Pressures of any sort should be removed if possible. Development of self-confidence is perhaps the most important factor. The pattern of the child's life should be adjusted so that he can experience the satisfaction of self-achievement and success within the limits of his capabilities. Under no circumstances should the child be shamed or punished because of a habit spasm.

*Impulsive tic* (Gilles de la Tourette's disease) is an infrequent condition which most often begins in late childhood or at puberty and occurs usually in neurotic families. It is probably more closely allied to hysteria and psychasthenia than to habit spasm. The symptoms are violent twitching or convulsive movements, usually of the muscles of the face and arms, but sometimes of other parts of the body. With the movements there are associated explosive sounds, such as a loud barking cough or the enunciation of certain words. The course is chronic, and the prognosis is not favorable, although the symptoms occasionally disappear if the psychologic disturbances are corrected.

## SCHOOL DIFFICULTIES

See also Reading Disorders, page 95.

Certain focal points in the life of every child are responsible for changes in behavior. Among such important situations is going to school, which involves many new experiences and extends over important years of child development. School difficulties stem from factors related to the adjustments required at the start of school and subsequently to new teachers and for many children to change of school groups. Separation from parents is another factor.

Every normal and healthy child and his parents will be faced with new problems arising out of going to school. But the child who is emotionally disturbed will be particularly pressed, and his behavior difficulties may now stand out more prominently and be-

come aggravated. Among the most frequent problems of school adjustment are those in the five, six and seven year olds who are coming to school for the first time and naturally are restless and overactive. When such children are asked to sit quietly for long periods of time, their motor activity is increased. Frequently such children are punished because they are inattentive and noisy. A more proper solution would be to arrange the school day so that there would not be unduly long periods of sitting quietly in one place. The first days of school are marked by anxiety on the part of children and parents. Some of this stems from the child's desire to be independent, but at the same time cling to his parent for protection. When teachers permit gradual separation of the child from his parent in the first several days by allow-

ing the parent to stay in the classroom or close by, there is less weeping at school and less fighting to remain at home. Night terrors and enuresis are often precipitated by the beginning of school.

The main problems in the school age child arise from difficulties in learning: some children are slow and have trouble learning to read, write and cipher; others are gifted and speed ahead of their classmates. Children in either group need special attention and handling if they are to benefit from school. If neglected, such children become trouble-makers by clowning or becoming aggressive, or withdrawing into a dreamlike world of their own. Most children have some trouble learning to read because this involves new use of their sensory systems in combination with a translation of symbols into thoughts, and finally into spoken or written words and sentences. The main cause of reading difficulty is trying to teach children who are not ready. Reading readiness cannot be determined solely by chronologic age. Although most children are ready at six to seven years, some may not be until one or two years later. As a rule, girls learn earlier and more readily than boys, and this accounts for a greater number of reading problems among boys. Children with visual or hearing defects will also have difficulty in learning to read. General poor physical health may prevent a child from being attentive and concentrating in the learning process. Teachers who are lacking in understanding of children or are frightening and punitive also block children in any kind of learning. The actual technique of teaching reading must also be individual-

ized. When children have trouble learning to read, they should have thorough physical examinations, particularly of the special senses, psychologic tests, including a measurement of intelligence, and an appraisal of what is going on at home and in the classroom. Children living under stressful home conditions may be poor learners. A slow learner who is placed in a classroom with many children will be denied individual attention from the teacher and may lag behind, appearing stupid when he is not.

*Treatment* of a learning difficulty depends on what may be done to remove the cause, as well as on procedures of therapy. These problems are more readily prevented than treated. Remedial teaching by friendly, understanding teachers frequently puts children at ease so that they are able, with individual guidance, to learn the fundamentals, and with this help frequently catch up with their age mates. Emotionally disturbed children require psychiatric treatment. The gifted child, just as much as the slow learner, needs to have a school program fitted to his abilities and capacities. Such planning should be the combined efforts of parents, teachers and others in the school, such as the psychologist and school physician.

Conduct disorders such as aggressiveness, lying and stealing, chronic running away from school, and delinquency warrant thorough investigation of home life, of activities in the school and during recreation, along with sympathetic and objective appraisal of the child by educators and other professional people, such as child guidance personnel.

## CONDUCT DISORDERS

### (AGGRESSION, DELINQUENCY)

In general this group of conditions comprises a range of conduct from aggression to passivity. Aggression that takes the form of antisocial acts is termed delinquency and is easily recognized as being pathologic. Less recognized is the fact that extreme passivity may be equally abnormal. Very good, ever-obedient, "too quiet," "never angry," overpolite and socially withdrawn behavior characterizes the latter. Between these extremes are mixtures of all kinds which make up the personality of the so-called average child. Most children at one time or another get into

difficulty in this field, and there is a growing and thoroughly healthy tendency for parents to turn to the pediatrician for help. The field is now so specialized, however, and involves so much of the disciplines of sociology and psychology that it can be dealt with here only in its broadest outlines.

*Etiology.* The problem child is invariably trying to solve a problem rather than be one. His methods are crude, and his conception of his problem may be faulty; but until the physician has patiently sought, and in sympathetic fashion found, what the child was

trying to do when he stole or played hooky or sulked at home or bullied the little ones, he is in no position to offer advice. There is little or no relation between conduct disorders and such recognized syndromes of illness as feeble-mindedness, glandular dysfunction, physical or mental asthenia, and the like. It is true that wretched home or neighborhood conditions may lead to delinquency in one child, while his siblings show no such reaction. Delinquency does not always occur in weaker children; it may occur in those strong and healthy enough to rebel in their own way against conditions which their brothers and sisters merely accept. Conduct disorders are not of necessity associated with any particular economic group. Many a child of wealthy parents is sent to a strict military school; had the family been poor, the child might well have been a candidate for a reform school.

The basic emotional needs of children are outlined on page 69. The physician will find that most of the conduct disorders appear in children who sense a lack in one or more of these. In getting at the problem it is most important that the child's confidence be gained. This may necessitate that the child come alone to the office; if so, the physician must be restricted in what he tells the parents to that which he and the child have agreed should be told. All attitudes of blame must be carefully shunned. It is a good policy to refrain from the two words that chiefly hamper work in this field, "admit" and "deny." A good basic principle is to use the technique of "the own story." In securing the story from the patient, one antedates the delinquency so that the conversation comes up to the trouble in the same natural sequence in which it actually occurred. Thus one does not say to the child, "Why do you wet the bed?" One begins, rather, before that period (e.g., before the arrival of the new baby) when there was no enuresis, for a short discussion of family relationships, playmates and satisfactions. The "own story" recapitulates the genesis of the trouble.

**Manifestations.** The child with a conduct disorder may have a wide variety of "symptoms," but in general they tend to fall into groups: (1) They may show themselves in the area of the child's "weak link." Thus, no matter what the initiating circumstance, the emotionally unstable child may show increased restlessness and tension with resultant truancy from school because he cannot sit still for hours. (2) They may manifest themselves in the higher reflexes, since these are

the most unstable mechanisms. So, with any precipitating unhappiness or social pressure, the child may become a bed-wetter, a poor reader or a stutterer. (3) The symptoms may be directed at vulnerable spots in the environment. For instance, dirty stories or sex play are exchanged with other children because the child can retaliate in these fields with more disturbance to his adult world than through almost any other interest. (4) The symptoms may be directed against those areas which the child feels have been unfair to him or are most vulnerable. Thus he wets the bed constantly at Aunt Mary's, but never elsewhere. (5) The symptoms may be specific to the problem. Thus he may steal because he is poor. He may run away because he thinks he is badly treated at home. As a general rule, reactions that are clearly specific to the problem involved are not common. The first three groups of symptoms are far more common than the last two.

Analysis of conduct disorders is further complicated by three other factors which may be related to the initial development of symptoms: (1) The appearance of the abnormal symptoms may be directly related to the exciting factor. For example, the child begins to play truant at eleven years of age, and this coincides with his entrance to the sixth grade, where there is a teacher with whom he does not "click." (2) The appearance of the symptoms may merely indicate that he has at last become old enough to fight back against a problem he has always had. For example, a child whose parents simply must have a successful, brilliant son may be seven or eight before he can begin to fight back against a family that has use for him only as long as he can be a shining support of their community position. These children will start bedeviling their parents with every sort of mischief at eight or nine, but the physician will search in vain for any specific cause at that time. (3) The most difficult situations to understand are those analogous to the supersaturated solution in chemistry. In such instances a slowly growing maladjustment which has been present for years is suddenly "crystallized out" by some purely chance incident. Thus a trip to a nearby city, a low mark in arithmetic or an unimportant accident may be the trigger mechanism for marked and persistent enuresis, stealing, truancy or running away from home. When the situation is unraveled, it will be found that the event which the parents and child thought to be causative was simply a chance precipitating

agent for a series of tensions that had been operating for a long time. Family tensions over stepparents or over such conditions as the child feeling that others are more deeply cared for than he may thus suddenly be precipitated into stubborn cases of conduct disorders.

The problem of conduct disorders becomes further involved, since it is a psychologic one directly related to the child's reaction to his world and because his methods of expression are limited. If, with the deepest humility and with knowledge that many an error will be made, the physician will try to analyze the situation with the child and the parent, he is doing the best that can be done.

**Prognosis.** In general, the outlook is good. In spite of the great amount of adult unhappiness and breakdown, it is amazing how many problem children become satisfactorily adjusted in later life. This is not to advise a policy of letting matters be, but rather to emphasize that there is a basic ortho-tendency that tends to produce adjustment, just as with physical illness persons tend to get well if given the opportunity.

**Treatment.** Treatment is a complex affair which must extend into every phase of the child's life. The pediatrician may undertake it because often it involves a simple and natural extension of his existing ties with the child. It may require collaboration, however, with teacher, pastor, scout leader, nurse or social worker, and an understanding of their approach to the child. An increasing number of psychiatrists are specializing in this field, and they may be utilized. There are two conditions which the physician must fully appreciate: (1) The treatment of behavior disorders will require far more time and, in general, will produce far less tangible and measurable results than the treatment of physical illness. (2) The child, justifiably, is fighting back against precisely those who employ the physician and pay the bill. A middle-of-the-road policy by the physician will not do; the issue requires a clear decision of what his stand will be.

Treatment should be preceded by an effort to divide the stresses into those that are individual and those that are situational. Unusually high intelligence, lameness or being a girl are examples of the former. Unhappiness between the parents, the community's racial attitudes, and rigid academic standards in the school belong to the latter. As the areas of attack are defined it is wise to set apart the elements about which nothing can be done.

It is amazing to see how much effort and false hope are expended on matters that are, *at this time*, beyond therapeutic manipulation. So far as is possible, the child must be a real partner in the formation of plans.

The social worker can be a source of help. In general, her training in problems of emotional tensions, family relationships and school pressures far exceeds that of the physician. When there are conflicting interests and drives in the family, she can be of the greatest assistance in seeing a good deal of the parents while the physician sees much more of the child (or vice versa). This allows each one to feel that he has a "friend in court." The social worker frequently has had a professional training equal to that of the physician and is not to be used just to carry out orders. If the relationship cannot be one of real cooperation, it had better not be entered into at all.

Two sets of problems occur so frequently that consideration must be given to them, even though it must still be on a superficial basis. A great many children have feelings of inferiority concerning a wide variety of problems. The physician must make the clearest distinction between a *feeling of inferiority* and an *inferiority complex*. In the former the child openly recognizes his difficulties, which can and should be as openly and sympathetically discussed with him. In the latter the child is making valiant efforts to hide his real inferiority—he bullies because his own group will not accept him, he blusters or shouts or plays truant so that no one else will see his real source of unhappiness. A complex must *always* be treated *indirectly*. The child has done his best to hide his "Achilles' heel," and the physician should not be a party to snatching off the camouflage. In these cases the physician has to guess at the real source of inferiority and to build the child up in this or some kindred field. Only then can the child afford to dispense with the complex.

The other problem is involved in the child's feeling about his own parents. No matter how kind or loving adopting or foster or stepparents may be, each child has to feel that in some way or other his own parents are really all right and that they really love him. Family tragedies occur, adoptions are necessary, divorce and remarriage are often wise steps. All persons, however, must recognize that not every material advantage will replace the child's overpowering need to feel the integrity of his own parentage. It is indefensible to point out to the child that his own par-

ents are, or have been, "bad." Children should never be removed from their homes with that sort of explanation. Moreover, the physician must be prepared to "spiritually stand by"

the child who with sullen bitterness or an uncontrollable flow of tears unfolds his awareness that his own parents were really bad or did not care for him.

## PSYCHOSOMATIC ILLNESS

Although most of the conditions which have been considered so far have both somatic and psychologic components, the disorders to be discussed in this section are more strictly designated as psychosomatic disorders. This group comprises but a few of the physical disturbances which have psychologic origins. The etiology of these illnesses is not necessarily limited to emotional factors, since often there is a mixture of physical (organic) and psychologic agents. The physician is prone to ascribe causes of ill health to either physical or psychologic elements rather than to *both*. The term "psychosomatic" is unfortunate in that to some physicians it represents a dichotomy of etiology and hence of treatment, which does not exist. The term should represent a two-way relationship, psychologic influences on the one hand being capable of causing physical illness, physical agents in turn being able to produce psychologic disturbances.

Emotional reactions may interfere with bodily function in every person, but the degree of interference and the location of the somatic dysfunction are variable and depend upon the individual. Inasmuch as there is a similarity in the psychodynamics of cause and effect of many of the psychosomatic disorders, and since some of the psychologic mechanisms which produce such symptoms have already been considered, only a few illustrative conditions will be reviewed.

One of the most frequent symptoms following an emotional upset is that of pain. The pain may be in any part of the body. Head pain is a common complaint. The discussion on headache which follows may be applied in general to pain in other parts of the body, and for that reason pain will not be discussed in terms of other organ systems. Other symptoms which appear almost as frequently as pain are those related to dysfunction of the gastrointestinal, cardiorespiratory and genitourinary systems. Nausea, vomiting, constipation and diarrhea are the more frequent gastrointestinal manifestations; breathlessness, asthmatic attacks, palpitation and discomfort

in the chest are prominent representatives of cardiorespiratory involvement; and incontinence and enuresis, as well as inability to void, are common urinary symptoms.

### HEADACHE

See also page 1073.

**Etiology.** Headache, although but a symptom, may depend upon many diverse conditions such as (1) organic diseases of the brain or meninges causing increased intracranial pressure; (2) infectious diseases, in which headache is often a prodromal symptom; (3) toxemia, dependent upon gastrointestinal disorders; poisoning by lead, alcohol, opium, and the like; metabolic disturbances such as hypoglycemia; chronic infections, including rheumatic fever; (4) disturbance of the cerebral circulation, often observed in anemia; and the congestive headache which accompanies pertussis, cardiac disease, difficult or delayed menstruation, sunstroke, and intense mental activity; (5) fatigue; (6) disorders of the special senses, of which eyestrain is the most frequent variety; these may be physical or psychologic in origin; (7) disorders of the upper respiratory tract, such as rhinitis, sinusitis and polyps (otitis may occasion an intense pain in the parietal or temporal region); (8) neurologic disorders; neuralgia, which is produced by many of the causes mentioned and is characteristically limited to the distribution of certain of the cranial nerves; (9) migraine (sick headache, hemicrania); and (10) emotional upsets.

**Diagnosis.** In young infants headache may be suggested by wrinkling of the forehead, rubbing of the head, restlessness and crying. In older children localized persistent pain in the head depends most often upon organic disease of the brain; when the cranial nerves are involved, the pain is likely to be neuralgic. Temporary headache with fever is most frequently caused by gastrointestinal disturbance or the onset of some febrile disease; periodic headache may be due to migraine;

frequently recurring headache may depend upon emotional conditions, anemia or eyestrain. The position of the pain is often a guide to the cause. Frontal headache suggests the presence of such conditions as eyestrain, acute infectious disorders, disease of the nose, anemia or gastrointestinal disturbances. Occipital headache suggests eyestrain or otitis.

**Treatment.** The cause must be sought and appropriate treatment instituted. Direct relief from the headache may be obtained by bodily and mental rest, and by the application to the forehead of cold cloths or an icebag. Acetylsalicylic acid (aspirin) in doses of 0.06 gm. (1 grain) per year of age up to five years may be effective, but its use should not detract from remedial therapy.

### MIGRAINE

Migraine is uncommon in infants and children. It is often inherited, apparently as a mendelian dominant factor. Among assigned causes are psychologic disturbances, toxemia, cerebral anemia, cerebral congestion, faulty metabolism, eyestrain and allergy. Migraine is more common in females.

**Clinical Manifestations.** Slight causes, such as fatigue, emotional upset or dietary indiscretion, may initiate an attack. The attacks occur at intervals of weeks or months, often on days when regular routine is not followed, and usually begin with prodromal symptoms such as vertigo or derangement of vision. Headache is intense and generally unilateral, and may be accompanied by photophobia, tinnitus, paresthesia, vertigo or temporary difficulty in speech. Ophthalmoscopic examination often shows blanching of the retina on the affected side. Zigzag, multicolored and scintillating scotomas, with hemianopsia persisting as long as five to thirty minutes at a time, frequently precede the onset of attacks of headache. After a few hours the pain is followed by nausea and vomiting, and then by deep sleep from which the patient awakens free from pain. In young children the headache may be a minor feature, but nausea and vomiting may be marked symptoms. Migraine may later replace attacks of recurrent vomiting.

**Treatment.** The treatment of migraine is far from satisfactory. Attacks can frequently be modified by such procedures as going to bed promptly at the onset and administration of ergotamine tartrate, phenobarbital or bromides. Ergotamine tartrate appears to be the most effective drug. It is best administered intramuscularly or, in severe cases, intra-

venously. The adult dose is 0.25 to 0.5 mg. The side effects of nausea, vomiting and numbness of the extremities may be distressing, and in overdosage it may cause thrombophlebitis, gangrene and anginoid attacks. Thiamine chloride in large doses, niacin (to produce vasodilatation) and repeated injections of histamine have been used, but their role is not well established. If allergy is demonstrated, efforts should be directed toward desensitization. Estrogenic and androgenic substances appear to have little or no place in the therapy of migraine in children. Prompt relief by inhalation of pure oxygen has been reported. Psychotherapy may be necessary.

### EATING DISORDERS

See also pages 112, 133, 647.

#### PICA

Pica, or perverted appetite, occurs most often in the first three years of life. It consists in the ingestion of a large variety of unsuitable substances, such as sand, earth, grass or other plants, wool from blankets, broken glass, animal droppings, paint from furniture, coal, ashes, or plaster from the wall. The crawling infant and the toddler particularly enjoy putting foreign matter to their mouths, partly for exploration of the outside world and partly to satisfy a craving for "mouthing" experience and sucking. This behavior in infants and preschool children (eighteen months to five years) often accompanies messy play activity and interest in dirt (fecal and other varieties). At times there is an underlying nutritional disturbance. In many instances the mental and general health is good; in others there is anemia and malnutrition, and it would appear there may be an unconscious attempt to obtain minerals or vitamins which are absent from the diet. The habit may occur in neurotic children and is common in mentally defective ones. There is a tendency for pica developing in infancy to cease spontaneously by the age of three or four years. The general health may be seriously affected by the harmful action of the objects swallowed; among the possibilities, lead poisoning may result.

**Treatment.** Treatment consists in preventing ingestion of the unnatural articles and in combating any abnormal conditions such as anemia and other specific and general nutritional disorders by appropriate dietary and therapeutic methods, as well as in permitting

infants to have extensive sucking, biting, chewing and other mouth, lip and tongue pleasure when they desire it developmentally.

### ANOREXIA NERVOSA

Usually this is a serious condition, characterized by a remorseless drive toward self-starvation. It may begin as early as eight or ten years of age, but is more commonly seen in its overt form during adolescence, usually in girls, when attempts at adjustments seem particularly stressful. The anorexia is often preceded by a conscious and deliberate refusal of food, even when there is good appetite. The child may also secretly begin taking medications in an attempt to lose weight. A chance remark by a teacher or relative about the child's being "fat" may initiate attempts at self-starvation. Careful history taking may elicit from the child, without much difficulty, her attitude about her body size and shape, and as the confidence of the physician is obtained there may be acknowledgment not only of secret practices related to diet and self-medication, but also of feelings toward parents, particularly the mother, and fantasies about sexual matters. Frequently there is evidence of open conflict between the patient and the family, especially the mother-daughter relationship. Misconceptions about conception and pregnancy are at the core of the sexual fantasies. There may be the belief (fear) that impregnation follows kissing and occurs through the mouth. Sooner or later, as the starvation is extended, a loss of appetite appears, along with amenorrhea and constipation. Vomiting which is self-induced is also occasionally seen. Family pressure in attempts to solve the problems tends to add fuel to the parent-child dissension. Occasionally the child acknowledges gains in the way of more attention and sympathy from the family because of her illness, but the unconscious motives are not revealed unless psychotherapy is utilized.

Occasionally episodes of refusal of food are replaced by periods of overeating and rapid regain of weight, to the point of real obesity. The over-all trend, however, seems to be one of obsessional preoccupation with diets, food values and weight gain, and attempts to reduce the body weight by food refusal, induced vomiting, spitting, and coughing up of huge amounts of sputum which are collected by the patient in a compulsive manner.

This condition must be distinguished from physical disease which causes malnutrition. This usually is not difficult, however, owing

to the prominence of the psychologic manifestations. Occasionally it is confused with Simmonds' cachexia.

*Treatment* consists first in correction of any electrolyte imbalance, and then beginning, slowly, increases in the diet. The child often requires hospitalization. Psychiatric consultation should be sought as early as possible not only to verify the diagnosis, but also to see that the medical management is as psychologically oriented as possible. Removal of the child from a stressful home may result in a favorable change, but recurrence of the abnormal pattern is common upon the return. Intense psychotherapy is always indicated. Unfortunately, even when this is expertly administered, the illness tends to be chronic and the prognosis grave.

## DISORDERS OF SLEEP

### INSOMNIA AND DISTURBED SLEEP

Although, in general, infants and young children require more sleep than those older, there is no fixed inverse relationship between age and hours of sleep (see p. 136). For example, a child of two or three years of age may for a while sleep fewer hours in a twenty-four hour span than he will when he is five to six years of age. This lessened sleep probably is related to events in the waking hours. It is well known that in this preschool age the child goes through a developmental phase when many things seem awry.

The physician will also need to explain to parents that irregular and restless sleep is natural during infancy; similarly, that the peculiar postures which the sleeping child assumes are physiologic, as is much of the pre-sleep behavior which annoys parents who are tired and would welcome earlier sleep hours for their children. Many parents regard the motor restlessness (crib cruising), head shaking, requests for food or water or for holding and rocking as deliberate demands for attention and carefully planned devices for teasing adult members of the household. This may be true in some instances, but this sort of behavior seems developmentally related to some of the emotional episodes of the growth process. For example, fear is engendered when the child passes through phases of rapid growth (e.g., in the prepuberal period); some of this fear may be expressed consciously, and some will appear in forms such as dreams. Consciously the child may beg his parents not to leave him as he falls asleep, or he may awaken at night to see whether his parents

are still there. Among other causes of disturbed sleep in infancy are hunger, pain, itching, local irritation, fever, unusual noises, undue excitement before the sleeping hours, and extreme fatigue. Some so-called nervous infants may be wakeful, either crying during the night or sometimes lying awake. Other possible causes are too much light, poor ventilation, too low or too high a temperature and insufficient or too heavy bedcovering or an uncomfortable bed.

Necessary and normal as sleep is, it is a complicated mechanism which is easily disturbed by any one of a variety of causes. If one is not sufficiently tired or is too tired, sleeplessness may result. In attempting to find the cause of disorders of sleep, two basic facts are worth remembering: (1) A child cannot be made to go to sleep, but reassurance and calmness are of prime importance. (2) Most families fail to come for help until everyone has become unduly concerned. The physician must make it clear that he can do nothing until the patient as well as his family has completely discarded the issue of "who's going to win."

In addition to the causes mentioned, certain others operative in older children are mental overwork, mental stimulation from the radio, moving-pictures or television; emotional excitement of any sort, even pleasurable, shortly before going to bed; and insistence upon sleep when there is no desire for it.

**Treatment.** Sometimes a light evening meal is helpful, but when hunger is the cause, the amount of food taken should be increased or the feeding schedule changed. A warm drink, as of milk, before retiring may have a good effect. A warm bath in the evening may have good results. The room should be darkened or a dim light allowed, according to the need. Everything should be avoided which centers the child's mind on the existence of sleeplessness. Soporifics may be used; they are occasionally helpful in breaking acquired inhibitions to sleep. Their use should not be a substitute for finding the cause and eradicating it, and they should be prescribed in gradually decreasing doses until they are discontinued completely. At times other members of the family may need hypnotics more than the infant, who, in spite of a restless night, enters upon the next day in good condition. Rocking infants in the arms of a parent or in an old-fashioned cradle may be all that is needed.

### EXCESSIVE SLEEPINESS

In feeble newborn infants there may be a disposition to constant sleep even without organic disease of the brain. Later, excessive sleepiness may be seen with exhaustion, at the onset or during the course of febrile diseases, in uremia, in hypothyroidism, in organic cerebral diseases accompanied by increased intracranial pressure, after epileptic convulsions, and as the result of drugs. Narcolepsy is discussed on page 1127.

### DREAMING AND SOMNAMBULISM

Infants may dream, as shown by the sudden startled screaming or evidently purposeful movements of the hands during sleep. Dreaming occurs particularly in children who are emotionally upset, in the restless and disturbed sleep of even mild illnesses, and after excitement. Often dreams are repeated night after night. Psychoanalysts believe that, even in childhood, dreams have psychologic importance. In somnambulism the patient, most often an older child, performs various systematic acts during sleep, actual walking not being a necessary feature. Talking during sleep may or may not be combined with somnambulistic acts.

The *treatment* of these conditions consists in searching for and removing any exciting cause. The temporary administration of sedatives may be helpful.

### TERRIFYING DREAMS

Certain influences may be operative such as are seen in ordinary dreaming, but in many instances the terrors occur repeatedly without such factors being discoverable. Two classes of cases have been described which have been arbitrarily termed "nightmares" and "night terrors." In the *nightmare* the child awakens from sleep in terror and perhaps confused, but ultimately he is cognizant of the dream which disturbed him. The dreams are not those resembling any actual experience, but are associated with fear. There is no recurrence on the same night. The attack comes on most often soon after going to sleep. In *night terrors* the attack usually occurs an hour or two after going to bed when sleep is deepest. Without previous warning the child suddenly sits upright in bed, bathed in perspiration, screaming and trembling; or he may get out of bed and be found sitting on the floor. Sometimes he repeats words or he may point with his finger, indicating the imaginary object which has frightened him.

Although he clutches at his mother or nurse, he does not recognize her, nor does he know where he is, and considerable time is required before he becomes quiet. Sometimes he sleeps again without returning to consciousness; in other instances he becomes partly conscious, cries, and then quickly falls asleep. The child may have no remembrance of the attack. The frequency of attacks varies; they may occur nightly or only at intervals of weeks or months. Epilepsy may at times closely resemble night terrors.

**Treatment.** Treatment of night terrors should be based on an appraisal of the child and his environment. Treatment of the dreams themselves should consist in awakening by the parents or by someone with whom the child feels secure. The child should be reassured verbally and encouraged then, or later, to recount the dream. It may be important to leave a dim light burning in the room or near it for the remainder of that night. A light evening meal and avoidance of bedtime excitement may be helpful. As a rule, late hours should be avoided. It may be necessary to change the milieu in which the

child is being reared or educated or in which he seeks recreation. An attempt should be made to improve his relationships with his parents, siblings and playmates. The pediatrician or general practitioner may initiate these studies, but often he will find it desirable to use psychiatrists or social workers who by training are especially prepared to provide more extensive study and treatment. Night terrors should be considered symptoms and viewed in the light of the total child.

#### DAY TERRORS

Attacks corresponding to night terrors may rarely occur in the daytime during the nap or even when the child is awake. He may be subject to night terrors also. The prognosis of day terrors must be guarded because of a more probable relationship with hysteria, epilepsy, mental or nervous diseases. In young children day terrors may be manifested by fits of violent screaming without discoverable cause. The element of anger must be excluded in making the diagnosis.

MILTON J. E. SENN

## DISORDERS IN LANGUAGE FUNCTION

Man's language function is highly complex. Its efficiency is dependent upon the individual's intelligence, personality and the functional adequacy of the central nervous system and of the peripheral organs of speech. It is a developed facility, not preordained to success, and never static.

Etiologic factors may be endogenous or exogenous, congenital or acquired, physical or psychotic. Etiologic generalizations are unwise, since causative factors are rarely limited to one category. The problem is not: Do certain factors produce language disorders in children?, but, What factors produce a particular disorder in an individual child?

Differential diagnosis is essential for the solution and treatment of any language disorder. Rarely are such problems "pure"; they are usually complex syndromes. Knowledge of the child's genetic, social, emotional and educational backgrounds, of his neurologic integrity, intelligence, achievements, and the dynamics of his personality organization is prerequisite to adequate evaluation. Superficial diagnosis usually means superficial

treatment. Diagnosis and treatment of the *whole* child are essential.

#### SPEECH DISORDERS

It is estimated that there are more than a million children in the United States between the ages of five and eighteen years' who are so defective in speech that remedial treatment and training are indicated. The incidence of each type of defect is greatest between the ages of four and eleven, and boys are affected more frequently than girls.

Speech disorders appear in three general categories. First in order of frequency are functional inefficiencies, such as stuttering, which have mixed or multiple causes. Second are defects originating in anatomic malformations such as cleft palate, malocclusion and harelip. Thirdly are dysfunctions produced by cerebral or cerebellar lesions, such as spastic disturbances, aphasia and central deafness.

**Speech Development.** The child's first vocal sounds, cooing, crowing and crying, do

not constitute speech; they are merely reflective of his general feelings. When he begins to develop an ego, a sense of himself, he will progress from the initial matrix of speech, babbling, to the production of sounds which have meaning and purpose. In the normal infant these primitive speech efforts appear at six to eight months of age. With continued development he will begin to imitate or echo and to associate objects, persons and experiences with the words he hears and is able to produce. By two years of age he should be able to make two- and three-word sentences. Prior to this he will have developed a competent sensitivity to emotional connotations in others' speech. From three to six years of age there is increasingly complex development; the child's psychology shifts from the autistic feelings of omnipotence to an acceptance of the reality of worldly forces. As this transition occurs the contents of his speech transform from initial questing to description, and finally to the understanding and use of abstract words and the expression of intellectual concepts. This progression is most variable and is dependent on intelligence, personality, and the social stimulation of his environment.

Failure to develop speech by twenty to thirty months of age demands evaluation. Nondevelopment may signify that previously noted prenatal or postnatal conditions are more serious than were initially considered. Speech failure is often a concomitant of mental deficiency, but at early ages this is a dangerous presumption. Neuromotor dysfunction, auditory disorders and a variety of psychologic disturbances, including childhood schizophrenia, may contribute to speech failure.

The *feble-minded child* who does not develop speech will exhibit behavior patterns characteristic of his mental level. His play will have little purpose. He will demonstrate only rudimentary understanding of speech, and will make little effort to communicate his needs by gesture. He will not necessarily be withdrawn or autistic, but will not relate well to others around him. The primary problem is determination of his basic intelligence. Speech therapy is slow and unrewarding in such children.

The *deaf child* of normal intelligence who does not speak will be purposeful in play, be obviously alert and attentive, and investigative in demeanor. He will pay little attention to speech or environmental sounds. His attempts to communicate will be principally

pantomimic. He is likely to be apprehensive, tense, easily irritable and overresponsive to tactile stimulation. His vocal sounds will have a metallic monotone of variable but emotionally dissociated pitch. When deafness is suspected, the child should be referred to an otologist and an audiologist. If the child is completely and permanently deafened, a special school, even though residential, is usually indicated. Without early training in lip reading and in the use of his speech musculature the child is unlikely to escape the eventual need for a complicated sign language.

*Aphasia*, due to cortical lesions, may be the cause of nondevelopment of speech. In receptive aphasia the child's auditory acuities may be normal, he may respond to environmental sounds, but he cannot interpret speech. In expressive aphasia the child has normal hearing and understanding of speech, but cannot formulate words despite normal motor function of the speech musculature. In central aphasia inner symbol function is so disturbed that neither receptive nor expressive functions develop. Early diagnosis is imperative.

Some children of normal intellectual and physiologic development may not acquire speech for psychologic reasons. An early illness, or other special circumstances, may centralize the attention of the parents and create situations wherein the child's needs are anticipated. Thus he may not need speech to fulfill his wants. In a few instances children may perversely use their muteness as a means of asserting power over the adults in their world. Some children may regress emotionally upon the arrival of a new baby and thus fail to develop speech at the expected time. There are also children who do not mature personality-wise: the autistic or schizophrenic child whose inner world is primary to him will not acquire speech, owing to his inattention to the world of reality.

Differential diagnosis should lead to a clear understanding of the child's mutism. In cases of organic etiology special techniques used by a qualified therapist can be helpful in accelerating speech. If the problem is psychologic, psychiatric management of the child and his parents is indicated. In some instances the problem may be merely a matter of familial slowness in speech development. Appropriate understanding by the parents of the nature of a child's speech failure is essential in any case. Efforts to evoke speech must *not* touch on the vital aspects of the child's life. Such efforts may be concerned with the

red wagon or the favorite doll, but not with such essentials as food, behavior training or other basic physical and emotional needs. Every attempt to have the child mimic a word should include first the child's visual attention on the speaker's mouth.

**Defective Speech.** Speech requires the synchronous activity of all the cortical areas which subserve the language function. The pertinent sensory regions record kinesthetic, auditory and visual stimuli. Normal speech depends first on the accurate recall and association of these engrams and kinesthetic patterns and then on their innervation into the proper sequential impulses which result in word production.

Defective speech may be secondary to an anatomic anomaly; malformations of the palate and of the larynx are readily discernible. Some of these lesions can be corrected surgically, but when it is desirable to delay repair, as it may be in the case of cleft palate, speech training should be undertaken at an early age.

There are many speech defects whose etiology is not primarily anatomic or neurogenic. These are the functional disorders wherein faulty articulation of consonants is the leading deficiency. The most common errors are made on s, z, th, l, r and w. Substitutions of w for r and r for l are not infrequent. Lipping, when not obviously due to malformation, is the result of faulty tongue action. Infantile speech may result from promiscuous use of baby talk at home. Speech therapy is not always indicated in these functional anomalies. Many children through good social contacts with their peers, and with consistently good speech models in their environment, will achieve spontaneous recovery.

Indistinct speech, nasal delivery, breathiness, hoarseness or weakened volume demands examination of the nasopharyngeal passages and larynx. Enlarged tonsils and adenoids may produce this type of speech defect. Cerebral or cerebellar disease may also be responsible for such dysfunction.

Deficiencies in articulation are also caused by central nervous system lesions. Slurred, mushy, slovenly articulation, or slow, hesitant, syllable-by-syllable or explosive delivery may be symptomatic of cortical disturbance or bulbar involvement. In some cases, if the affecting lesion is not catastrophic, general improvement without therapy may be expected. Speech therapy and other remedial measures can, however, hasten improvement. Treatment

should utilize to the fullest extent all residual function.

## AUDITORY DISORDERS

Auditory disorders are responsible for certain defective speech characteristics. When there is definite hearing loss throughout the auditory range, certain deficiencies in speech may be expected. There will be a harsh, monotonous metallic quality to the child's voice, accompanied by little inflection and emphasis, and poor articulation. The deafened child rarely uses his voice for pleasure or ideational communication. He uses it to call attention to himself, and the product is impelled by fear, anger or discomfort. The greater the hearing loss, the more the child's speech is disturbed. When the hearing loss involves high frequency sounds, the child's speech will be defective through errors of omission such as of sibilants and soft sounds in words. There will also be poor differentiation of short vowel sounds. With low frequency deafness vowels and the deeper speech sounds will be faulty. Auditory evaluation should precede any speech therapy. Successful speech therapy depends on the skill of the therapist, on the psychologic status of the child, on his environment, and on whatever can be done to compensate for his auditory dysfunction.

## STUTTERING

Stuttering is an inability to speak freely, owing to incoordinate and spasmodic action of the musculature involved in speech. Two types of spasm may be observed: the tonic, resulting in complete blocking of speech, and the clonic, producing a repetitive disturbance ("c-c-c-can't"). Both types are frequently intermingled, and the initiating motor impulse often overflows in comparable spasmodic action into other neuromuscular functions, such as jerky movements of the feet, hands, arms and shoulder. The muscular paroxysms usually occur simultaneously with the child's efforts to speak. In the tonic type, at the instant of relaxation, the "pent-up" word is exploded, followed by rapid speech. In the clonic type the sound which is being repeated is finally blended with the remainder of the word. Occasionally, whole words and phrases are repeated. There are frequent periods, particularly in the milder cases, when the child can speak freely and naturally.

Stuttering occurs in approximately 1 per cent of all children of school age. It is the

most common functional speech disturbance and has a greater incidence among boys than girls, the ratio being about six to one. It occurs at any level of intelligence, appearing between the ages of two and ten years. It is at times accompanied by functional difficulty in other language facets, such as reading, spelling and handwriting.

Until recent years there was no general agreement about the underlying causes of stuttering, but some unity about therapy. There is increasing evidence that stuttering is symptomatic of profound emotional disturbance, although some continue to assume that the emotional aspects are secondary to disturbances within the central nervous system. Proponents of each of these concepts achieve notable therapeutic success by means of treatment methods based on their particular beliefs, but many stutterers go through life with their defect.

Orton proposed the theory that stuttering is due to fluctuating failure in kinesthetic integration resulting from lack of unilateral cerebral dominance for language controls. He believed that mixed motor dominance signified some deviation in the individual's establishment of this unihemispheric mastery. Studies, however, do not support the contention that there is a significant disparity between stutterers and nonstutterers in laterality of handedness. Interference with the use of the child's favored hand may or may not bring about an onset of stuttering. Furthermore, such interference cannot be postulated to interfere with the inherent development of cerebral controls. It is the child's adverse emotional reaction to an enforced change of his natural pattern that may bring on stuttering. Parents should always be advised not to attempt to influence the development of handedness.

There are two somewhat arbitrary etiologic categories in stuttering. These are termed primary and secondary disturbances; both have to do with emotional factors. The primary disturbance appears when the child begins to speak; this designation is also assigned to children who stutter before the age of four or five years. There is considerable evidence that these children have an extremely deep emotional disturbance. The primary stutterers, without prolonged psychotherapy, have a poor prognosis. The disturbance of the secondary stutterer is more likely to be in the category of hysteria, his adjustments are not so deeply neurotic, and his prognosis is more favorable under psychiatric management.

Whether stuttering is considered neurogenic, psychogenic or complex in its etiology, the patient will be initially unaware of the mechanisms creating his disorder. He is conscious only that he stutters. There is thus set in motion a reactive anxiety which in itself disturbs his emotional balance and contributes to the chronicity of his disorder.

There are many schools devoted to the stutterer. Much of the therapy is functional, being aimed at turning the person toward voluntary control of the speech apparatus. Most often such treatment is of only temporary benefit. The obvious reason for such disappointing results is failure to take into account the underlying psychologic disturbance.

**Treatment.** Before a rational plan for the treatment of stuttering can be devised, the child's behavior pattern must be thoroughly understood. Such an appraisal requires evaluation of his physical, intellectual and emotional status in relation to the many inherited and environmental factors which have been responsible. Whenever possible, it is recommended that evaluation comprise both verbal and nonverbal psychometric and standardized tests of educational achievement, analysis of language function and personality inquiries, such as the Rorschach and other projective tests. In evaluating the child's personality the physician should not accept the results of the usual questionnaire type of "inventory," since they may be misleading.

In therapy first consideration should be given to the prevention or alleviation of reactive anxiety. In the very young no attention should be paid to stuttering. There must be no nagging or ridicule, no undue sympathy or special attention. Everything possible should be done to eliminate adverse psychologic conditions in the home environment. Parents should be guided toward a better understanding of the disorder and of their contributions or reactions to it, so that they may assist, either directly or indirectly, in therapy. In school, regardless of a possible ebullience on the part of the stutterer to answer questions, it is usually wise to curtail, but not eliminate, oral recitation until the child has shown considerable improvement. On the other hand, participation in dramatics, in which parts are memorized and adverse reactions are not apparent, is sometimes therapeutic.

Most therapy is threefold: physical, emotional and functional. Optimal results are usually obtained through coordinated efforts

in these areas. Prompt attention should be given to defects in general health. The young stutterer usually has a low threshold of nervous fatigue, and needs help in planning his daily regimen, with particular attention to diet, exercise and rest. Factors in the environment which produce undue emotional reaction or exciting situations and which act as a drain upon nervous energy should be reduced to a minimum.

In general, psychologic management should be aimed at creating in the patient insight and understanding of his disorder. The physician should be on guard against the amateur mental hygienist in such cases. When there is obvious psychopathology, the stutterer should be treated by an experienced psychiatrist. Speech therapy is contraindicated in such cases until the psychiatrist feels it is warranted. The speech correctionist should always be chosen for experience, personality and philosophy.

## READING DISORDERS

Reading is the most complex facet of language function. It is not an isolated entity. It calls upon the integrity and precise association of the major portions of the cerebral organization. It is a perceptual, creative, interpretive enterprise commanding the positive use of an inquiring intelligence. Emotional, mental and physical health immediately influence, or are affected by, success or failure in reading. The most important concept about reading is the fact that it is a dynamic expression of the entire personality function.

A reading disorder may be defined as an inability to read with skill and effective understanding at a level commensurate with the person's experience and general intelligence. The degrees of difficulty range from mild retardation to total failure. Rarely is it a pure syndrome; poor spelling, vocabulary deficiencies and handwriting problems are often associated. There is usually an accompanying lag in those school subjects dependent on reading. Children thus handicapped are frequently able, however, to do relatively well in arithmetic computation and other non-reading areas.

Difficulties in the achievement of reading efficiency have the greatest incidence among children with language function disorders. It is reported that 10 per cent of the school population are handicapped in varying degrees by dysfunction in this sphere. There is

an unequal sex distribution, the male to female ratio appearing as 6:1. The largest number of cases appear in the years from seven to fourteen, from the second to the eighth grade. When comprehensive diagnosis is achieved, over 75 per cent of reading disorders reveal causative personality imbalances, about 10 per cent are related to faulty educational procedures, from 2 to 3 per cent are neurogenic, and the balance result from combinations of these and other conditions. Evidence in support of Orton's theory that delayed establishment or instability of unilateral cerebral dominance as a major cause of reading disability is dwindling. No longer are mixed motor dominance, left-eyedness and right-handedness, for example, considered important symptoms in these cases.

Adverse personality factors are becoming recognized as an important cause, not necessarily a secondary result, of reading disabilities.

For the preschool child the average American home is a matriarchy. The major portion of the early training efforts, cultural atmosphere and emotional climate are influenced by the mother. The child's primary struggle for selfhood must, of necessity, be with the mother, owing to the father's daily absence. The child's initial school years are an extension of this situation; when these early relationships are reasonably healthy for the child, he usually does not present learning problems. When they are adverse, he lags in learning, and generally his chief deficiency is in acquiring reading ability. It is notable that these conditions appear with slightly higher incidence in the moderate and upper income brackets than in the lower brackets. Influences appearing frequently are premature weaning and intense struggles of 'will over early feeding. Overstrict socialization efforts, through the "mother knows best" attitude, appear in over 15 per cent of these cases. Prolonged babying is likewise a factor. The mother who domineers through emotionalism, possessiveness or intellectualism, who criticizes the child for failure to meet her standards, who frequently admonishes, "You could do better," is contributing to a probable reading retardation. Teachers may do likewise.

Children with reading disorders are less well adjusted socially than successful readers. The psychologic factors responsible for the reading failure, not the deficiency itself, are usually at fault. There are four patterns of behavior among these children: the crushed, inhibited, unspontaneous, plastic child; the

hyperactive, thumb-sucking, enuretic immature child; the subtly negativistic, willful non-conformist; and the "I can't because I'm too dumb" type. They all proclaim their desire to succeed with reading. Accompanying psychosomatic complaints are frequent, such as allergies, colitis, erratic appetite and untoward irritability. Everyone is worried about the child and brings a great deal of pressure, consciously or otherwise, to overcome his learning problem.

The functional *symptoms* may vary, but most typical are the perceptual errors, appearing in oral reading and spelling, of transposition or reversal of letter orientation and sequences in words ("was" for "saw," "god" for "dog," "post" for "stop"). Accompanying confusions of letter-sound associations are prevalent. There is no regularity to the child's production of these errors; he will commit them repetitively, capriciously and spasmodically. He will demonstrate no ostensible control over his confusions. These are perceptual errors and are often referred to as "mirror vision," "mirror reading," alexia or "associational reading difficulty," and were termed by Orton "strophosymbolia." These errors do not stem from peripheral visual anomalies. They are of "central" origin, and their etiology is more likely to be psychogenic than neurogenic.

Other significant error patterns may predominate in oral reading. The child may offer "wild guesses" having little relation to a given word configuration or its relation to the context. He may omit words, or substitute one more personally familiar to him than the one in print ("boat" for "ship," "come" for "go"). Again, he may add words of his own to embellish the context. When these errors predominate, there is the possibility of faulty educational training, but more probably the pattern is symptomatic of psychologic maladjustment. When these "symptomatic" errors are not readily observable, and yet the child does not grasp what he reads, inadequate method and narrow vocabulary may be suspected. The child may be facile at pronouncing words with little recognition of their meaning or be limited in his facility to put words together into meaningful concepts. Here, again, adverse personality and educational factors may be presumed.

*Differential diagnosis* of reading disorders is imperative. Ophthalmologic studies should be required. The general health status should be examined; if neurologic study seems indicated, the inclusion of an electroencephalo-

gram should be considered. The pediatrician, in referring his patient to a reading clinic, should insist upon a thorough psychologic evaluation. Such a study must include a test of general intelligence by the revised Stanford-Binet scale, the Wechsler intelligence scale for children or the Wechsler-Bellevue intelligence scale. Secondly, educational achievement testing should contain quantitative and qualitative analyses of both oral and silent reading, of vocabulary levels, spelling, arithmetic computation and problem solving. Functional tests of visual and auditory perception are useful. Personality evaluation by "projection" tests such as the Rorschach and Szondi tests and the apperception instruments are imperative; interpretation by means of questionnaires or "inventories" can only be superficial. The results of these tests should be interpreted by a qualified person. Without integrated information from each of these categories the child may be given only perfunctory treatment and ultimately have serious difficulties inimical to his own welfare and that of the community as well.

*Treatment* should be based on the diagnostic findings and be planned in relation to the child's *total* situation. Some reasonable explanation to the child of his difficulty is essential. Reassurance of the parents and a lifting of their anxious pressure on the child are important. Both mother *and* father should be given as clear and practical an understanding of the nature of the problem and of the therapy as is possible. There is no case of reading disorder wherein this is not a primary need. This is particularly imperative when psychiatric management is indicated. Psychotherapy and concomitant parental guidance will be more effective if wanted by all concerned. Such treatment is likely to be less efficient, and may even fail, if approached with reluctance and hostility by either child or parents.

A variety of effective educational techniques are applicable to these deficiencies. None of these methods will lead to achievement if the remedial reading teacher stresses adherence to procedure and forgets that a good relationship with the child is vital to the success of the method. This fact is often forgotten by the eagerly striving educational specialist. If the pediatrician is treating the child concomitantly for psychosomatic complaints, he would do well to evaluate this factor and advise accordingly.

Remedial reading techniques may consist

in the kinesthetic, whole-word "tracing" procedures devised by Fernald. Phonetic systems are also useful in many cases. In neurogenic problems the Fernald system or the methods of Goldstein, Strauss and Lehtinen or of Benda may be utilized. Choice of method should be the decision of the therapist in relation to the diagnosis and the child as a person.

Often retardation in reading is used as an explanation for the child's failure in school subjects dependent on reading. The child, parents and teachers all expect academic success with the acceleration of reading proficiency. Experience reveals that this does not always occur. In such cases the disorder was initially a symptom of psychologic maladjustment; although the patient responded to the symptomatic treatment, he may still be unable to achieve initiative and perseverance in academic areas.

With comprehensive, differential diagnosis and appropriately designed treatment, most psychogenic reading disorders can be successfully overcome. The time required is variable,

ranging from six months to two years with a minimum of two treatment hours per week. The disorders resulting from organic factors do not respond rapidly to therapy, and the prognosis as to the child's eventual efficiency must be guarded.

NUTRITIONAL REQUIREMENTS

A clear understanding of the fundamentals of nutrition is basic for the adequate medical supervision of children.

WATER

Water is second only to oxygen as an essential for existence; lack of it results in death in a matter of days. The water content of infants is relatively higher (75 to 80 per cent of the body weight) than of adults (65 per cent). Assuming that body water comprises 70 per cent of the body weight, 5 per cent is blood plasma, 15 per cent is interstitial fluid, and 50 per cent is intracellular fluid. Fluids provide the principal source of water; some is obtained from the oxidation of foods (mixed diets yield about 12 gm. of water per 100 calories) as well as of body tissues.

Requirements for water are related to caloric consumption and to the specific gravity of the urine. It is necessary for the infant to consume much larger amounts of water per unit of body weight than the adult, but when calculated per 100 calories of intake, the amounts required are practically the same (see Table 14). The daily consumption of fluid by the healthy infant is equivalent to 10

to 15 per cent of his body weight in contrast to only 2 to 4 per cent by the adult. Perhaps more than by chance, the natural food of infants and children is high in water content, most of the solid food in the child's diet containing 60 to 70 per cent water, and many of the fruits and vegetables, 90 per cent.

Little if any water is absorbed directly from the stomach, but absorption continues through the entire intestinal tract. Some water may go directly into the lymph stream, but most is taken into the blood stream. The quantity of water in the interstitial compartment changes

kidney produces a solution with a greater osmotic pressure than that of the internal environment, it is able to preserve the fluid and electrolyte equilibrium of the body; only 1 per cent of the filtrate of the kidneys enters the bladder.

CALORIES

The unit of heat in metabolism is the large calorie (C), defined as the amount of heat necessary to raise the temperature of 1 kilo-gram of water from 15° to 16° C. The pro-duction of heat varies with the oxidation of different foods, so that measuring the amount of oxygen consumed is the common method for measuring the amount of food oxidized and the heat produced. Estimates of heat pro-duction obtained from measurements of the end products of oxidation, carbon dioxide and water approximate those obtained by direct calorimetry.

There is great variation in the energy needs of children at different ages and under vari-ous conditions (see Fig. 21 and Table 17). The average expenditure of energy by the child of six to twelve years of age is approxi-mately as follows: maintenance of basal metabolism, 50 per cent; specific dynamic action of food, 3 per cent; growth, 12 per cent; physical activity, 25 per cent; and loss by way of feces, about 10 per cent.

Basal metabolism is measured at room

considerably in order to maintain homeo-stasis within the intracellular and vascular compartments. The interchange of water among these compartments is dependent on their respective protein contents and electro-lyte concentrations.

Depending upon the rate of growth, about 0.5 to 3 per cent of the fluid intake is re-tained. Somewhat less than 50 per cent of it is estimated to be eliminated through the kidneys, 3 to 10 per cent through the intes-tinal tract and 40 to 50 per cent by evapora-tion through the lungs and skin. Because the

FIG. 21. Total daily expenditure of calories with approximate distribution between individual factors in relation to age and weight

temperature (20° C.) ten to fourteen hours after a meal, with the patient physically and emotionally quiet. For each degree (centigrade) of fever the basal metabolism is increased approximately 10 per cent. The basal requirement in infants is about 55 calories per kilogram of body weight per day and decreases to 25 to 30 calories at maturity. The term *specific dynamic action* (SDA) refers to the increase in metabolism over the basal

rate brought about by the ingestion and assimilation of food. Protein may increase the metabolism as much as 30 per cent above the basal level (except when protein is being deposited in tissues), whereas fat and carbohydrate, which have a "sparing" effect on the SDA of protein and upon each other, cause an increase of only 4 to 6 per cent, respectively. Practically, the theoretic SDA is probably never attained. In infants about 7 to 8

Table 16. Function, Effects of Deficiency and Excess, Requirements and Sources of Water, Calories, Proteins, Carbohydrates and Fats

Type of Nutrient	Function	Effects of Deficiency	Effects of Excess	Requirements	Sources
Water	Structure of cells; matrix for cellular changes; medium for ions; transport of nutrients and waste products; regulation of body temperature	Thirst, dryness of tongue, dehydration, anhydremia, high sp. gr. of urine, loss of kidney function (acidosis, uremia, anuria, death)	Abdominal discomfort, headache, cramps (water without salt), intoxication, convulsions, edema and circulatory failure	See Tables 15 and 17 Related to calories consumed; greater in hot weather	Water as such All foods
Calories	Energy for basal metabolism (body temperature, muscle tonus, circulation, respiration, peristalsis, glandular function, vegetative function); specific dynamic action of food; growth and physical activity	Underweight, malnutrition	Overweight	See Figure 21 and Table 17 Varies with body surface (weight and height) and age	4 C./gm. CHO 4 C./gm. Prot. 9 C./gm. Fat
Proteins	Supply amino acids for growth and repair of tissue cells; sols for osmotic equilibrium; ions in acid-base balance. With prosthetic groups to form hemoglobin, nucleoproteins, glycoprotein and lipoproteins. Enzymes, hormones, cellular respiratory substance, antibodies. Protective structures (nails and hair). Source of energy	Lassitude, abdominal enlargement, edema; depletion of plasma proteins, negative nitrogen balance (no clinical syndrome due to lack of specific amino acid)	Prolonged high protein intake not harmful	See Table 17 4 to 6 times greater per unit body wt. for infant than adult. See footnote (p. 101) for requirements of essential amino acids	Milk, eggs, meat, fish, cheese, soy beans, peas, beans, cereals, nuts, lentils
Carbohydrates	Readily available source of energy (body heat and muscular work), antiketogenic, structure of cells, antibodies, source of stored calories, conversion to fat, resynthesis of amino acids, roughage	Ketosis (if protein intake less than 15% of calories or in starvation); underweight, if total calories are low	Overweight; galactosemia (if unable to metabolize galactose)	To supply 25 to 55% of calories	Milk, cereals, fruits, sucrose, syrups, starches, vegetables

Table 16 (Continued)

Type of Nutrient	Function	Effects of Deficiency	Effects of Excess	Requirements	Sources
Fats	Concentrated reserve energy; physical protection for vessels, nerves, organs; insulation against changes in temperature; structure of body tissues, cell membranes and nuclei; vehicle for absorption of vitamins (A, D, E and K); stimulates appetite; aids satiety (delays emptying time of stomach); avoids necessity of ingestion of large bulk of foods; spares protein, vitamins A and B <sub>1</sub> ; supplies essential fatty acids	Lack of satiety (craving for fat), underweight	Overweight	Minimal not known, usually supplies 35% of calories Perhaps 2-3% of calories as linoleic acid	Milk, butter, egg yolk, lard, bacon, meat, fish, cheese, nuts, vegetable oils

per cent of the total caloric intake goes to SDA, whereas in older children on an ordinary mixed diet it is not likely to be more than about 5 per cent of total intake. The energy necessary to build body tissue (*growth*) is estimated to be the difference between the calories ingested and those expended for other purposes. The average requirement for *physical activity* is 15 to 25 calories per kilogram of body weight per day, peak utilizations being as high as 50 to 80 calories for short periods of time. The amount of energy-producing food lost in the stools (*unused portion*), except when absorption is impaired, is not more than 10 per cent of the intake.

Although caloric requirements can best be predicted from the surface area rather than from age or weight, the final criteria for meeting the child's needs depend upon the growth pattern, the sense of well-being and satiety. As indicated in Figure 21, the daily requirement is approximately 100 to 120 calories per kilogram of body weight for the first year of life, with subsequent decreases of about 10 calories per kilogram for each succeeding three-year period. Periods of rapid growth and development near puberty require increased caloric consumption. The average distribution of calories in a well balanced diet is as follows: protein, 15 per cent; fat, 35 per cent; carbohydrates, 50 per cent.

Table 17. Approximate Daily Requirements of Children for Calories, Protein and Water

Age in Years	Calories*		Protein	Water*	
	Per Kg.	Per Lb.	Gm./Kg.†	Ml./Kg.	Oz./Lb.
Infancy. ‡	110	50	3.0±	150	2¼
1-3.	100	45	2.5-3.5	125	2-
4-6.	90	41	2.5	100	1½
7-9.	80	36	2.5	75	1.0+
10-12.	70	32	2.0	75	1.0+
13-15.	60	27	1.5	50	¾
15+	50	23	1.0+	50	¾
Adult	40	20	1.0	50	¾

\* At least 10 per cent variation.

† To convert gm./kg. to gm./lb., divide by 2 and subtract 10 per cent of the quotient. Thus 4 gm. kg. is equivalent to 1.8 gm./lb.

‡ First month lower; first 6 months relatively higher than last 6 months. Breast-fed infants require lesser amounts of protein.

## PROTEINS

Protein, the predominant solid structure of the body, constitutes about 20 per cent of the body weight of the adult. An essential nutrient in the formation of cell protoplasm, it is found principally in the muscular and nervous systems and in the visceral and glandular tissues. It forms an integral part of most body fluids and secretions.

The kind, number and arrangement of the amino acids in a protein molecule determine the characteristic of the protein. Twenty-two amino acids have been identified; at least eight have been found to be essential for infants: threonine, valine, leucine, isoleucine, lysine, tryptophane, phenylalanine and methionine. From animal studies, histidine and arginine also appear to be essential.\* If protein is replaced by a mixture of amino acids in the diet, there is an increased need for calories. New tissue cannot be formed unless all the essential amino acids are present in the diet. Hence the absence of only one essential amino acid will result in a negative nitrogen balance.

Complex protein structures are broken down to proteoses, peptones, simple peptids and finally to amino acids in the digestive process. The hydrochloric acid of the stomach acts upon the protein to form acid metaprotein, which is soluble in an acid medium and can be readily acted upon by rennin and pepsin. Rennin changes casein of milk to paracasein, which pepsin hydrolyzes along with other proteins to proteoses and peptones. In the alkaline medium of the intestine, trypsin from the pancreas hydrolyzes these proteoses and peptones to dipeptids, tripeptids and tetrapeptids and to some amino acids, and peptidase from the intestinal juices carries digestion of these to the amino acid stage.

\* Studies with infants indicate the minimum requirements for the amino acids to be as follows: tryptophane, 30 mg. per kilogram for growth and nitrogen retention in infants; isoleucine, 90 mg. per kilogram for nitrogen balance in infants; methionine, 100 mg. per kilogram; threonine, 45 to 58 mg. per kilogram; phenylalanine, 90 mg. per kilogram; leucine, 200 mg. per kilogram; histidine, 30 mg. per kilogram. Data regarding lysine are not as adequate, but the requirements may approximate 100 mg. per kilogram per day.

As might be expected, the requirements for infants per unit of body weight are much greater than for adults and are greater for men than for women. Approximate minimum daily requirements for the essential amino acids in terms of grams per day for men and women respectively are: tryptophane, 0.25, 0.16; phenylalanine, 1.10, 0.22; lysine, 0.80, 0.50; threonine, 0.50, 0.31; valine, 0.80, 0.65; methionine, 1.10, 0.55; isoleucine, 0.70, 0.45.

Minute amounts of certain proteins may be absorbed unchanged as evidenced by immunologic reactions, but it is the hydrolytic products, the amino acids, which are normally absorbed through the intestinal mucosa. The amino acids are carried to the liver by the portal circulation and from there are distributed by the systemic circulation and are taken up rapidly by the tissues. Though amino acids are probably not stored as such, the excess absorbed and those from the breakdown of tissue proteins undergo deamination. The nitrogenous portions are converted to urea and are excreted by the kidneys. The carbon from amino acids is oxidized much as the carbohydrates. Some amino acids are glycolytic, others ketogenic. The absorption of protein is so efficient that little nitrogen is found in the stools.

The total plasma protein in the normal child ranges from 6 to 7.5 gm. per 100 ml., with somewhat lower values in newborn and premature infants. The albumin-globulin ratio is usually 2 to 1, fibrinogen varying from 0.1 to 0.4 gm. per 100 ml.

## CARBOHYDRATES

The greatest portion of the caloric needs of the body is supplied by carbohydrates, which also supply the necessary bulk of the diet. Carbohydrates are stored chiefly as glycogen in the liver and muscles, but probably make up not more than 1 per cent of the body weight. The infant's liver is one tenth that of the adult and the muscle mass one fiftieth; hence the infant has only a small fraction (approximately one twenty-sixth) of the glycogen reserve of the adult.

Carbohydrate is utilized as dextrose (glucose), but is consumed in various forms: the monosaccharides (dextrose, fructose, galactose), the disaccharides (lactose, sucrose, maltose) and the polysaccharides (starches, dextrins, glycogen, gums, cellulose). Pentoses are poorly absorbed.

Through a series of enzymatic reactions in the digestive tract, carbohydrates are broken into simpler structures. Amylase of the saliva breaks starch molecules to dextrins and maltose. The hydrochloric acid of the stomach hydrolyzes disaccharides to monosaccharides. Pancreatic amylase hydrolyzes the polysaccharides, while the enzymes of the intestinal glands complete the splitting of disaccharides: maltose to two molecules of dextrose; sucrose to dextrose and fructose; lactose to dextrose and galactose. The monosaccharides are rap-

idly absorbed. During absorption the phosphoric acid radical combines with hexose sugars in the intestinal mucosa and the hexose-phosphates formed are again broken into their component parts. Some dextrose may be oxidized directly, as in the brain and heart, but the absorbed monosaccharides are carried to the liver in the portal circulation and then to the systemic vascular system.

Most of the absorbed sugar is converted to glycogen in the liver, although glycogenesis also occurs in other tissues of the body. Up to 15 per cent (usually about 10 per cent) of the weight of the liver and 3 per cent of the muscle may be glycogen; there are also small amounts in the skin and in practically all other organs of the body. Glycogenolysis in the liver yields glucose as the chief product, whereas glycogen breakdown (glycolysis) in the muscle yields lactic acid. The over-all oxidation of glucose is complicated, having two phases, the anaerobic (glycolysis) and the aerobic (tricarboxylic acid cycle). In the former, glucose is broken down to pyruvic acid; in the aerobic cycle pyruvic acid is completely oxidized to carbon dioxide and water. Insulin, as well as pituitary and adrenal hormones, is involved in these processes, and nicotinic acid, thiamine and pantothenic acid take part in the enzymatic reactions. Carbohydrate which is not oxidized or stored as glycogen is converted to fat.

The major carbohydrate metabolic disorders are diabetes mellitus, glycogen storage disease and galactosemia.

## FATS

### (LIPIDS)

*Simple lipids*, esters of fatty acids with various alcohols, are the most abundant fats in the body and in food, the most common being triglycerides. *Compound lipids* (lecithin, cephalin, sphingomyelin, cerebrosides, sulfa and amino lipids) contain nitrogen bases, phosphoric acid, sugar, sulfur or amino groups with fatty acids and alcohol. *Derived lipids* from these two groups are separated out by hydrolysis; they include cholesterol, choline and saturated and unsaturated fatty acids.

Alkaline secretions with small amounts of free fatty acids and bile salts, together with motions of the intestinal tract, emulsify fat in the intestine. The lipolytic enzymes of the intestinal tract and pancreas hydrolyze the emulsified fat to fatty acids, glycerol and monoglycerides and diglycerides. The latter,

with bile salts, assist in absorption. Resynthesized fat passes directly into the lymph system and empties into the venous circulation by way of the thoracic duct. Naturally occurring fats contain straight-chain fatty acids, both saturated and unsaturated, varying in length from four to twenty-four carbon atoms, most of them containing sixteen or eighteen. The degree of absorption varies in general with the melting point and the degree of unsaturation.

**Essential Fatty Acids: Linoleic and Arachidonic Acids.** Human beings do not synthesize fatty acids with two double bonds. In healthy children dienoic, trienoic and tetraenoic acids constitute, on the average, 30.9, 1.9 and 12.7 per cent of the total fatty acids. In severely malnourished children these values average 11.6, 2.5 and 8.0, respectively. Hansen and co-workers observed that young infants on diets lacking linoleic acid frequently exhibit changes in the texture and appearance of the skin and an increased frequency of stools. When fat is absent from the diet, both man and experimental animals require more calories. The serum levels for *dienes* (linoleic) and *tetraenes* (arachidonic) acids decrease significantly, whereas the *triene* (3 double bond) fatty acids increase as compared with these levels in infants receiving milk containing linoleic acid. They observed that the addition of only 1 to 2 per cent of the calories as linoleic acid caused a rapid clearing of the skin, a restitution of the blood serum pattern and a decrease in caloric consumption.

## MINERALS

The ash content of the fetus is low; at the time of birth it constitutes only about 3 per cent of the body weight. It increases continuously throughout childhood, both absolutely and relatively, so that in the adult the mineral content is forty times greater than in the newborn, whereas the body weight is but twenty-three times greater. In the adult the ash content is 4.35 per cent of the body weight, 83 per cent of which is in the skeleton and 10 per cent in the muscle. It has been estimated that for each gram of protein retained, 0.3 gm. of mineral matter is deposited. The important electropositive elements are calcium, magnesium, potassium and sodium; the electronegative, phosphorus, sulfur and chlorine; the important inorganic complexes, iron and iodine; and the trace elements,

Table 18. Function, Effects of Deficiency and Excess, Requirement and Sources of the Nutritionally Important Minerals

Name	Function	Effects of Deficiency	Effects of Excess	Requirements	Sources
Calcium	Structure of bone and teeth, muscle contraction, nerve cell irritability, coagulation of blood, cardiac action, production of milk	Osteoporosis and osteomalacia, rickets (related to phosphorus loss), tetany	Dietary excess not harmful	Related to phosphorus ratio and vitamin D intake and sunshine. Roughly 1.0 gm./day (50-70 mg./kg.) provides daily retentions of 10-20 mg./kg.	Milk, milk products, eggs; leafy vegetables (0.2-0.3 gm. daily)
Magnesium	Structure of bone, ionic balance (intracellular), enzyme metabolism, regulation of nerve impulses and muscular action	Low plasma magnesium tetany in rats, dogs, cattle and possibly in human beings	Not harmful	Unknown; average consumption 2-400 mg. daily; estimated requirement 13 mg./kg./day	Green vegetables (in organic combinations with chlorophyll), milk, meat
Potassium	Structural protoplasm; regulation of nervous and muscular activity; intracellular action in acid-base equilibrium	Deficiency only under abnormal conditions, e.g., diarrhea, burns, shock, alkalosis, ACTH and cortisone therapy, and familial periodic paralysis, abdominal distention, weakness, paralysis, cardiac irregularities and electrocardiogram changes suggest deficiency	Heart block at serum levels of about 10 mEq./L.; such levels unlikely with normal renal function. In Addison's disease, excess may precipitate crisis	1 to 2 gm. daily	Natural foods, as vegetables, meat, milk
Sodium	Ionic equilibrium, osmotic pressure, irritability of neuromuscular system, small amounts in muscle and cartilage cells	Dehydration, loss of renal function; muscular cramps with excessive sweating; low intake contributes to crisis in Addison's disease	Edema, if excessive administration of parenteral fluids, particularly in premature and small infants with immature renal function	Estimates for daily intake as NaCl by parenteral routes: Newborn... 0.25 gm. Infants... 1 gm. Children... 3 gm. Adolescents and adults... 6 gm.	Foods, table salt
Phosphorus	Structure of bone, muscle and nerve tissue; absorption of carbohydrates; intermediary mechanisms of muscle activity; absorption of fat; buffer in acid-base equilibrium; with cephalin in formation of thrombin in clotting of blood	Unknown; related with calcium and vitamin D to rickets, osteomalacia and osteoporosis	No harmful effects known with adequate renal function; possibility of tetany during recovery from rickets due to excess in diet	55 mg./kg. with adequate calcium and vitamin D allows for retention of 6 to 8 mg./kg. per day; daily intake of 1.5 gm. recommended for Ca:P ratio of 1:1.5; the ratio is lower in infancy	Milk, milk products, meat, beans, cereal grains

Table 18 (Continued)

Name	Function	Effects of Deficiency	Effects of Excess	Requirements	Sources
Sulfur	As a constituent of certain amino acids: in keratin, pigment of epidermal tissues (melanin), bile acids, mucous secretions and vitreous humor, connective tissue, endocrine secretions (insulin) and enzymes, heparin and glutathione; with sugars to form glycoproteins and with lipids in nervous tissue	Unknown	No known significance; urinary acidity due to sulfates	Intake of 0.5 to 1 gm./day; ideal intake not known	Protein-containing foods
Chlorine	Acid-base equilibrium, osmotic equilibrium	Deficiency occurs in severe diarrhea, vomiting or excessive sweating. Administration of parenteral fluids of glucose without saline may produce deficiency, particularly in treatment of burns	Not likely under ordinary dietary conditions. Excessive parenteral administration of NaCl may lead to edema formation	2-3 gm. daily. Greater in pathologic conditions associated with dehydration, acidosis and adrenal cortical hormone disturbances	Foods, table salt
Iron	Structure of hemoglobin and other iron-containing compounds, related to oxidation mechanisms	Anemia (iron deficiency type): hypochromic, microcytic	None from dietary excess. Poisoning by medicinal iron (p. 1389)	In early life 0.4 to 1.0 mg./kg./day. For the older child, 0.2 to 0.4 mg./kg./day. Intake recommended varies from 6 mg. daily for infants to 16 mg. for adolescents (Table 19)	Meat, eggs, liver, green leafy vegetables, whole grains, legumes, beans, peas
Iodine	Manufacture of thyroxine, which is essential for regulation of energy metabolism	Simple goiter, endemic cretinism	No clinical significance in man	Children, 40-100 micrograms daily; adults, 100-200 micrograms daily	Iodized salt, common table salt with 0.01% potassium iodide; supplements needed in goiter areas
Fluorine	Related to hardness of bone and teeth; possible suppression of bacterial action, especially <i>Bacillus acidophilus</i> in saliva	Tendency to dental caries	Mottling of teeth, fluorosis	In drinking water, 0.7 part per million is sufficiently high to prevent dental caries, but low enough to avoid mottling	

Table 18 (Continued)

Name	Function	Effects of Deficiency	Effects of Excess	Requirements	Sources
copper	Catalyst in hemoglobin formation	Occasionally hypochromic anemia	Not harmful	For infants and children the diet should contain about 0.1 mg. of copper per kg. body weight; adults, 2 mg. daily	
zinc	Presence in enzymes, carbonic anhydrase, uricase and insulin substantiates its essentialness	Unknown	Unknown	Unknown	Similar to iron, but more abundant in milk

fluorine, copper, zinc, manganese, cobalt, silicon, selenium, boron, nickel, aluminum and arsenic.

**Calcium.** The bones and teeth contain 99 per cent of the calcium of the body. Absorption of calcium takes place in the upper part of the small intestine and is influenced by the intake of phosphorus and vitamin D, by the pH of the intestinal contents and by the amount of fat and such radicals as oxalate in the intestinal mixture. Under usual circumstances deposition in bone is a rapid and active process, calcium being constantly withdrawn and redeposited. Normally the plasma calcium level is 5 to 6 mEq. per liter (10 to 12 mg. per 100 ml.). The hormones of the parathyroid glands directly influence calcium metabolism: hypofunction decreases the serum calcium and increases the serum phosphate, and hyperfunction has the opposite effect. Calciferol and irradiated 7-dehydrocholesterol probably affect the level of the serum calcium indirectly through their influence on phosphate resorption by the kidney tubules; dihydrotachysterol raises the level of the serum calcium directly. Thyroxin, estrogens and adrenal cortical hormones also have an effect on calcium metabolism. About 10 per cent of ingested calcium is excreted in the urine and about 70 per cent in the stool; 15 to 25 per cent is retained, depending upon the rate of growth.

**Magnesium.** About three fourths of the magnesium in the body is in the skeletal structure, with most of the remainder in the muscles; there are only small amounts in other tissues. In some respects it is related in its metabolism to calcium, and in others the actions are antagonistic. Most of the magnesium is in the cells of the body, and there are only small amounts in extracellular fluids.

In the growing child about one sixth of the intake is retained, about two thirds is excreted in the stool, and the remainder is excreted in the urine. The plasma level is 1 to 3 mEq. per liter (0.5 to 3.5 mg. per 100 ml.), and the intracellular magnesium concentration is about 40 mEq. per liter.

**Potassium.** The potassium within the cellular structure of an infant is estimated to be 100 times greater than that in the extracellular compartments; it is concentrated to the greatest extent in muscle cells and erythrocytes. Of the total intake, about 8 per cent is retained by the growing child, about 80 per cent is excreted through the kidneys, and the rest in the feces. About one third of that retained is gradually lost through the sweat glands, and at times even more may be lost by this route. The blood level is maintained between 4 and 5.5 mEq. per liter (16 to 22 mg. per 100 ml.).

**Sodium.** Sodium is almost completely absorbed from the gastrointestinal tract; when the daily intake is about 2 gm., about 10 per cent is retained; about 98 per cent of that excreted is found in the urine. Of that retained, about 12 per cent is eventually lost in sweat. The blood concentration is maintained at about 142 mEq. per liter (330 mg. per 100 ml.).

**Phosphorus.** Phosphorus is widely distributed in the body as inorganic phosphate and as organic compounds, about 70 per cent of it being in the skeleton. While it is readily absorbed in its organic form in the upper part of the intestinal tract, there is evidence that some is later excreted into the lower intestine. Ordinarily about 31 per cent of that ingested is excreted in the feces and about 55 per cent in the urine; average retentions during childhood are about 14 per

cent, with much greater retentions during periods of rapid growth. In breast-fed infants about 55 per cent of the ingested phosphorus is retained, and in artificially fed infants, owing to the higher phosphorus content of cow's milk, about 25 per cent. The level of inorganic phosphate in the serum of children is 2.2 to 3.7 mEq. per liter (4 to 6 mg. per 100 ml.), which is definitely higher than in adults. The organic phosphorus of whole blood (mainly in the erythrocytes) is 35 to 50 mg. per 100 ml. It is present as phospholipids, such as lecithin, cephalin and sphingomyelin, and as organic esters, such as glycerophosphates, phosphoglycerates and hexosephosphates, and in nucleic acid.

**Sulfur.** Sulfur, as a component of the amino acids with a sulfhydryl linkage (SH), methionine, threonine, cysteine and cystine, is an integral part of the proteins of the body. It is present in taurocholic acid, in the pigment melanin, in glycoproteins, in tendons, cartilage and connective tissue, in mucous secretions and vitreous humor, in endocrine secretions (insulin), in respiratory pigment (glutathione), in the nervous system (combined with lipids as sulfolipids and sulfatides) and in vitamins (biotin and thiamine). In organic form it plays a minor role in acid-base equilibrium and is also concerned with detoxicating mechanisms of the body.

**Chlorine.** About two thirds of the blood plasma anions is chloride, and about one eighth of the chloride present in the body is in the plasma. Chloride is abundantly supplied in food and table salt. Approximately 1 per cent of that ingested is lost through the feces, 91 per cent in the urine. The remaining 8 per cent is retained, about one fifth of it being gradually excreted with sodium and potassium through the skin. The chloride level of the blood serum is 99 to 106 mEq. per liter (350 to 380 mg. per 100 ml.).

**Iron.** There are approximately 3 gm. of iron in the body of the average adult, about 58 per cent of which is in the blood as hematin combined with globin to form hemoglobin; about 15 per cent serves functionally in the tissues such as in chromatin material and in cytochrome; approximately 20 per cent is stored, principally in the liver, spleen and bone marrow with smaller amounts in the kidneys and skin. Iron is ingested in both organic and inorganic forms, the inorganic form appearing to be more readily utilized. It is estimated that the child retains 0.6 mg. of elemental iron daily, or 4.5 gm. during his

entire growth period. Absorption appears to be dependent upon the body stores; most of that not absorbed is lost in the stool; very small amounts are present in the urine (0.02 mg. per liter) and lesser amounts in sweat and desquamated cells. The body's ability to conserve iron is amazing. The amount of iron in the blood serum is 50 to 180 microgram per 100 ml. Each gram of hemoglobin contains about 3.4 mg. of iron. Iron released from destroyed hemoglobin is used over and over again. Copper may act as a catalytic agent and may be essential for hemoglobin formation, particularly in fetal life. Other metals, such as arsenic, zinc, nickel, cobalt and manganese, have a similar influence.

**Iodine.** Iodine is present in the body in amounts of 20 to 50 mg. It is consumed in both organic and inorganic forms and is readily absorbed as iodide from the intestinal tract. It is selectively withdrawn from the blood by the thyroid gland, which is able to concentrate iodine to a degree 10,000 times greater than any other tissue. The gland contains about 0.4 gm. of iodine per 100 gm. of tissue (average weight of thyroid is 25 gm.). In the gland inorganic iodine is converted to protein-bound iodine.

About 40 to 80 per cent of ingested iodine (varies with iodine content of water and soil) is excreted through the kidney; a considerable amount may be lost in perspiration, and some through the lungs. The amount in the blood is 6 to 13 micrograms per 100 ml.

Marine's success in preventing goiter in the children of Akron by feeding them 0.2 gm. of sodium iodide daily for two weeks each spring and fall indicates that sufficient iodine can be stored to meet requirements for a relatively long time.

**Fluoride.** Fluoride is heavily concentrated in the enamel of teeth and to a less extent in bones. Carious teeth have a lower concentration than healthy teeth, and dental caries is less frequent in areas where mottling of teeth results from a heavy intake of fluoride. The addition of fluoride salts to communal water supplies is responsible for a definite decrease in the incidence of caries in children.

**Copper.** Though the exact role of copper is not known, in invertebrates it is present in hemocyanin, which has oxygen-carrying properties; in vertebrates it seems to act as a catalyst in the transformation of iron into oxygen-carrying hemoglobin. Copper is found in greater concentration in the very young than in older animals, and is stored princi-

pally in the liver. About 24 mg. per kilogram are present in the liver of an infant as compared with 4 mg. per kilogram in that of the adult. Excretion in the urine varies from a trace to 0.7 mg. in twenty-four hours. In adults the average amount in the blood is 0.132 mg. per 100 ml.

**Zinc.** Zinc, present in the human body to about the same extent as iron, is most abundant in the pancreas, liver and kidney, with a higher rate of storage in young than in older subjects. The average daily intake is 12 to 20 mg. in adults, nearly all of which is found in the feces, though small amounts are excreted in the urine. Balance studies with children show that there is a slight retention, suggesting that there may be actual requirements for zinc. Rats show evidence of deficiency by impaired growth with definite changes in the skin and fur.

**Manganese.** Studies with rats and chickens indicate that manganese plays an essential role in the activation of enzymes and of certain catalytic actions. Manganese, whether given orally or parenterally, is excreted mostly in the feces. Balance studies suggest that the diet of preschool children should contain 0.2 to 0.3 mg. per kilogram of body weight per day.

**Cobalt.** Though it is not known whether cobalt deficiency produces any symptoms in a human subject, in sheep and cattle characteristic symptoms of emaciation and anemia develop. Man's requirement is not known; there is some increased erythrocyte formation after the administration of cobalt in the treatment of patients with anemia, particularly in that associated with infection.

**Silicon.** Silicon is present in all tissues, constituting as much as one ninth of the total ash. Because the amount present in the skin decreases with age, it is believed to be related to its elasticity. Blood levels in man are as high as 16 mg. per 100 ml. Some silicon is excreted in the urine, but most in the feces. Silicosis has not been known to result from a dietary source.

**Selenium.** There has been some interest in this element because in areas where there is high concentration of selenium in the soil and food, animals have severe nutritional disturbances. The significance in human beings is not known.

**Boron, Nickel, Aluminum, Bromine, Arsenic.** These elements exist in minute traces in man, but have not been shown to be significant in either human or animal nutrition. Boron is essential for plants; nickel delays insulin hypoglycemia; aluminum in excess may interfere with absorption of phosphorus; and bromine and arsenic are important pharmacologically.

VITAMINS

**Vitamin A.** Vitamin A and its precursors, the carotenoid pigments, are abundantly supplied in the average diets of children. Vitamin A ( $C_{20}H_{29}OH$ ) is a primary aliphatic alcohol of high molecular weight with an optically inactive beta-ionone ring. Vitamin  $A_1$  predominates in the tissues of salt-water fish; vitamin  $A_2$ , in fresh-water fish. They are formed in the animal organism from the precursors or the provitamins obtained from plants. The most important of the carotenoid

Tables 17 and 19 are adapted from recommendations by the Food and Nutrition Board of the National Research Council. Slight variations were made in order to state the amounts necessary for each 3-year period after infancy in direct arithmetic progression.

*Table 20. Functions, Effects of Deficiency and Excess, Requirements and Sources of Nutritionally Important Vitamins*

<i>Name</i>	<i>Function</i>	<i>Effects of Deficiency</i>	<i>Effects of Excess</i>	<i>Requirements</i>	<i>Sources</i>
Vitamin A	Supplies complex which unites with protein to form rhodopsin (visual purple) and iodopsin (visual violet), substances in the retinal cones and rods; development and maturation of epithelial cells	Nyctalopia (night blindness) and hemeralopia (inability to see in bright light): stratified, cornified epithelium with keratinized surface resulting in xerosis, Bitot's spots, xerophthalmia and ultimately keratomalacia; phrynoderma and keratosis pilaris	Hypervitaminosis A: bone changes, liver and spleen enlargement, anemia, drying and peeling of skin; lipemia when given in excess amounts as vitamin concentrates; carotenemia from excess carotenoid pigments (xanthosis cutis)	2500-5000 I.U. daily. Requirements greater in children having faulty fat absorption or liver disease (see Table 17)	Milk, milk products, egg yolk, beef, mutton, fats, liver, fish, and liver oils (percomorph, halibut, burbot, tuna, shark, cod), apricots, carrots, peaches, tomatoes, sweet potatoes
Thiamine	Combines with phosphates to form thiamine pyrophosphate, a coenzyme (cocarboxylase) which readily removes pyruvic acid	Accumulation of pyruvic acid in tissues and blood; diminution of the coenzyme cocarboxylase. Degeneration of the myelin sheath of nerves with fragmentation of the axis cylinder and wallerian degeneration: loss of striations and cloudy swelling or degeneration of the muscles supplied by these nerves; beriberi	Unknown	0.4 to 1 mg. (see Table 17)	Milk, liver, pork, other meats, fish, eggs, cheese, green vegetables, fruits
Riboflavin	Respiratory enzyme system in combination with phosphoric acid and protein; these enzymes include cytochrome reductase, d-amino acid oxidase; probably plays a role in metabolism of iodopsin	Decrease in the concentration of enzymes which contain riboflavin; symptoms include vascularization of the cornea, glossitis, cheilosis and sebaceous eruption about nose	Unknown	0.6 mg. for infant to 2.0 mg. for adolescent (see Table 17)	Milk, liver, pork, other meats, fish, eggs, cheese, green vegetables, fruits
Niacin	Coenzyme (1) diphosphopyridine nucleotide, also known as coenzyme I or cozymase, and (2) triphosphopyridine nucleotide, coenzyme II or coferment	Pellagra	Produces no untoward symptoms	4-16 mg. from infancy to adolescence (see Table 17)	Liver and meat, best sources; milk small amount; plants, poor sources, except whole wheat and peanuts

Table 20 (Continued)

Name	Function	Effects of Deficiency	Effects of Excess	Requirements	Sources
Vitamin C	Necessary for structure of intercellular ground substance; the reversible oxidation-reduction reaction concerned with cellular respiration; metabolism of aromatic amino acids in growing organisms	Abnormalities in the collagen of all fibrous tissue, in the matrix of bone, dentin and cartilage and all non-epithelial cement substances, including the vascular endothelium, scurvy	Unknown	Artificially fed infants need vit. C. Breast milk contains 4-7 mg. of ascorbic acid per 100 cc. Requirement varies with age of patients (see Table 17)	Citrus fruits, tomatoes and other fruits and vegetables
Vitamin D	Metabolism of phosphorus and calcium by making them available to skeletal tissue	Rickets, osteomalacia, osteoporosis, infantile tetany and possibly dental caries	As dietary supplement: excess of concentrates may produce toxic symptoms as well as excessive calcification of soft tissues, including kidneys, with consequent renal damage	400 800 I.U. (see Table 17)	Fish liver oils, "concentrates," irradiated foods; sunshine or ultra-violet irradiation to the body
Vitamin K	Essential part of prothrombin formation, hence of blood coagulation	Prolonged prothrombin time, resulting in bleeding	Not important	None under usual circumstances; necessary with liver disease when lack of bile in intestinal tract and in faulty fat absorption	Chlorophyll, present in many green leafy vegetables; hemp seed, soy bean oil, rice bran

pigments are beta-carotene (one molecule of which can form two molecules of vitamin A), alpha-carotene, gamma-carotene and cryptoxanthin. Vitamin A is absorbed with greater ease than the carotenoid pigments, absorption being influenced by such features as the amount of fat in the diet and of bile in the intestine. Part of the absorbed vitamin A is transported by the lymph system to the venous blood, and some appears to go directly to the liver, where the greater part is stored (about 95 per cent of the vitamin A in the body). Rhodopsin in the rods is broken down in bright light into vitamin A aldehyde (retinene) and protein; part of the complex is destroyed. In the dark, visual purple is resynthesized, in part from the old products and in part from new vitamin A.

**Vitamin B Complex.** A group of so-called water-soluble vitamins have come to be known as members of the vitamin B complex. Of these, niacin, riboflavin and thiamine, which tend to be found together in nature, are essen-

tial in the nutrition of children. The component members of the vitamin B complex supply a necessary prosthetic group to form one or more of the coenzymes which function in enzyme systems concerned with cellular respiration and with carbohydrate, protein and fat metabolism.

**Thiamine.** The hydrochloride of thiamine is a pyrimidine-thiazole compound ( $C_{12}H_{17}N_4OS.HCl$ ). Thiamine, the first discovered component of the vitamin B complex, is known as vitamin B<sub>1</sub>. It is found in the circulating blood, is readily excreted in the urine and feces, but is stored in the body only to a limited extent. There is some evidence that synthesis in the intestinal tract may occur, at least in certain species.

**Riboflavin.** Riboflavin is the only vitamin discovered and isolated before a clinical entity due to its lack was described; hence this entity bears the name ariboflavinosis. A pigment showing a greenish-yellow fluorescence in water solution, riboflavin ( $C_{17}H_{20}N_4O_6$ ) has

a side chain ribityl radical derived from the alcohol d-ribitol. Its oxidation yields d-ribose (adonitol). The other part of the complex is iso-alloxazine. Riboflavin in nature may be combined with phosphate, or with adenine as flavin adenine dinucleotide; both forms of riboflavin are coenzymes in many metabolic reactions.

**Niacinamide.** Niacin ( $C_6H_5O_2N$ ) (3: pyridine carboxylic acid) as the amide combines with phosphoric acid, adenine and ribose to form two coenzymes used for transferring hydrogen in the fundamental oxidative life processes in the cells of the body. It is stored in the tissues of the body, principally the liver, and is excreted in the urine as the methyl derivative.

**Vitamin C.** Ascorbic acid, a 2, 3-dienol-L-gul furano lactone ( $C_6H_8O_6$ ), is the chemical name for vitamin C, which is found in the blood in concentrations from 0.4 to 1.2 mg. per 100 ml. of plasma when the dietary intake is adequate. A certain amount, related to its concentration in the tissues, is continuously excreted in the urine. Ascorbic acid is necessary for the structure of intercellular ground substance in which tissue cells are embedded and cemented together.

**Vitamin D.** The natural diet of the child is more likely to be lacking in vitamin D than in any other food essential. There are, perhaps, ten or so sterols which have vitamin D activity, the most important of which are activated ergosterol (vitamin D<sub>2</sub>, viosterol, calciferol) from vegetable sources and irradiated 7-dehydrocholesterol (vitamin D<sub>3</sub>), a naturally occurring vitamin from animal sources. The body is able to activate its own precursors by exposure to sunlight.

Vitamin D is fat-soluble and is absorbed with fat from the intestines, its absorption being influenced by the fat of the diet as well as by bile salts. Vitamin D is especially concerned with phosphate metabolism, and there is some evidence that it may also have a direct effect on calcium metabolism.

**Vitamin K.** Vitamin K is concerned with prothrombin production. A number of substances with a quinoid structure have vitamin K activity. Vitamin K<sub>1</sub> ( $C_{31}H_{46}O_2$ ) (2-methyl-3-phytyl-1, 4-naphthoquinone) has been isolated from alfalfa, and vitamin K<sub>2</sub> ( $C_{41}H_{56}O_2$ ) (2-methyl-3-difarnesyl-1, 4-naphthoquinone) has been isolated from putrefied fish meal. A synthesized compound, 2-methyl-1, 4-naphthoquinone, under the nonproprietary name of menadione, appears to have the greatest antihemorrhagic activity.

In its naturally occurring form it is fat-soluble and apparently is absorbed readily from the upper part of the jejunum. Lack of bile predisposes to a deficiency. The small amount stored is in the liver. Vitamin K is apparently synthesized in the gastrointestinal tract, probably by bacterial action.

**Pyridoxine.** This vitamin (also known as vitamin B<sub>6</sub>;  $C_8H_{12}O_3NCl$ ) is a complex which includes pyridoxine, pyridoxal and pyridoxamine. The phosphorylated forms of the latter two are the active coenzymes for certain transaminations and decarboxylations. Convulsions in infants may be associated with low intakes of pyridoxine. It is fairly abundant in ordinary diets, but little is known of actual human requirement.

**Pantothenic Acid.** Pantothenic acid ( $C_9H_{17}O_5N$ ) occurs in bound form in many tissues in the body and functions as coenzyme A in acetylation reactions and in certain key reactions of the oxidative phase of metabolism. Because of its wide distribution in tissue cells and its importance in animals, it is undoubtedly essential for man; however, no symptoms due to its lack have been described in infants and children. Apparently it is abundant in average diets.

**Biotin.** A cyclic derivative of urea, biotin ( $C_{10}H_{16}O_3N_2S$ ) on oxidation yields adipic acid. It has been referred to as the universal vitamin, since it is found in all living tissue. Biotin deficiency has been produced experimentally in man with a diet containing 30 per cent of the calories as desiccated egg white. Biotin is abundant in the average diet; actual requirements are not known.

**Choline.** The basic substance choline ( $C_5H_{15}O_2N$ ) is present in lecithin and is believed to be a factor in the mobilization of fatty acids in the body. Methionine and betaine are closely related to choline physiologically and also act as a source of labile methyl groups, especially in the absence of choline. These substances are known as lipotropic factors in the prevention of fatty degeneration in the liver.

**Inositol.** Hexahydroxycyclohexane, inositol ( $C_6H_{12}O_6$ ), is combined in plants as phytin, a calcium magnesium salt of inositol phosphoric acid. It is found in body tissues and fluids. Its function appears to be related to that of fat; it may act as a lipotropic substance in the prevention of certain types of fatty liver in the rat. Little is known about human requirements for it, although it is abundant in the usual diet.

**Para-aminobenzoic Acid.** Para-aminoben-

ic acid ( $C_7H_7O_2N$ ) is a constituent of folic acid.

**Pteroylglutamic Acid (Folic Acid).** Pteroylglutamic acid, sometimes called the *L. casei* factor, was formerly known as vitamin  $B_c$  and vitamin M. It has clinical significance in the development and treatment of a macrocytic type of anemia in infants. There are indications that a derivative of this vitamin, formyl folic acid (citrovorum factor; folinic acid), may be the metabolically active form of the vitamin. Aminopterin, a biologic antagonist of folic acid, is used to prolong remissions in leukemia.

**Vitamin  $B_{12}$ .** Vitamin  $B_{12}$  (cyanocobalamin) has been isolated from refined liver extract and appears to be the antipernicious anemia factor of the liver. It appears to be necessary for "labile methyl" metabolism. In animals it stimulates growth, but no conclusive evidence for a similar effect in children has been demonstrated.

**Vitamin E.** Alpha tocopherol ( $C_{29}H_{50}O_2$ ) is the most important of the substances having vitamin E activity, which include beta, gamma and delta tocopherols. The relation of vitamin E to human nutrition is not known, but limited evidence suggests that tocopherol may be related to muscle metabolism in man.

**Citrin.** Formerly called vitamin P, citrin is found in paprika and the rind of citrus fruits. It consists of two compounds, hesperidin and eriodictin, and is said to be concerned with capillary resistance, but its significance in man is not known.

## MISCELLANEOUS FACTORS

**Roughage.** Roughage is indigestible vegetable fiber. Macy found that amounts as high as 170 to 300 mg. per kilogram per day appeared to cause no difficulty. Most children who receive average well-balanced diets obtain sufficient amounts of roughage.

**Digestibility.** The relative amount of a given food available for assimilation by the body is high in most of the common food classes: carbohydrate is 97 per cent; fat, 95 per cent; and protein, 92 per cent. Vegetable fats and proteins have lower values. Cooking is a factor in digestibility. For example, the boiling of milk reduces the size of the protein curd and renders it more digestible for infants; by contrast, heating destroys vitamin C activity.

**Satiety.** The ingestion of a meal should provide a sense of well-being. Whole milk, cream, eggs and fatty foods have a high satiety

value; sugar increases the flow of gastric juice and delays emptying of the stomach, thus also increasing satiety. Bread and potatoes have relatively low satiety values, as do lean fish, vegetables and many fruits.

**Availability.** Low economic status, more than any other factor, limits the availability of essential foods and is probably the greatest single cause of malnutrition in children. Diets of families in the lower income brackets are likely to be deficient in milk, fruits and vegetables. A suggested method for planning low cost meals is to divide the money available for food into fifths: one fifth each for vegetables and fruits; milk and cheese; meats, fish and eggs; bread and cereals; and fats, sugar and other food adjuncts.

Geographic distribution also influences the availability of foods, the tendency being for a population to consume foods indigenous to

Table 21. Recommendations for the Content of the Daily Diet of the Healthy Child

Proteins	2 gm. per kg. of body weight
Fat	} ... Sufficient to meet caloric needs
Carbohydrate	
Minerals	
Calcium	1.0 gm.
Phosphorus	1.5 gm.
Iron	16.0 mg.
Iodine	Trace
Vitamins	
A	5000 I.U.
Thiamine	1 mg.
Riboflavin	2 mg.
Nicotinic acid	10 mg.
Ascorbic acid	60 mg.
D	400 to 800 I.U.

### COMPOSITION OF THE SATISFACTORY DAILY DIET

Milk	¾ to 1 quart
Meat, poultry or fish	1 serving (5 to 6 per week)
Liver	1 serving or more per week
Eggs	1 daily (5 to 6 per week)
Vegetables (1 raw, 1 pigmented)	2 or more servings
Fruits (1 fresh; noncitrus, and 1 citrus or tomato juice)	2 or more servings
Butter	2 to 4 tsp. or more
Bread and cereals (whole grain or reinforced)	Sufficient to meet caloric needs
Vitamin D concentrate	400 to 800 I.U.
Salt (iodized)	For seasoning

Adapted from the Food and Nutrition Board of the National Research Council.

its own area. The effect of geographic factors on deficiency diseases is evidenced in the high incidence of goiter owing to a deficiency of iodine in certain areas and by the relationship between dental caries and fluorine in communal water supplies.

## FEEDING OF INFANTS

The successful management of infant feeding requires practical interpretation of specific nutritional needs and of the widely varying limits of the normal baby's appetite and behavior with regard to food. Since the establishment of feeding habits as well as personality patterns begins at birth, and since the newborn period is a time of great emotional tension for the mother, it is important that she be helped to understand his needs as well as her own.

Fathers and other members of the household are too often neglected by physicians in

their approach to the problems of infant care. Time is rewardingly spent in conferences at the hospital or at home with emphasis on reassurance, on explanation of simple procedures, and on the philosophy of adjusting the family's activities, within reasonable limits, to the infant's needs. The physician can learn much about the personality and expectations of both parents which is invaluable in helping to avert physical and psychological problems centered around feeding.

The majority of feeding difficulties of the first few years of life are the result of abnor-

nal and unpleasant child-parent relationships, most of which are avoidable.

With the present emphasis on "self-regulating" infant feeding schedules, it is natural that uncertainties result concerning the extent to which the infant shall determine his routine. There is reasonable agreement that better child-parent relationships develop when the infant's natural habits serve as the basis for determining his daily habits, but there remains a need for the experienced physician to guide the parents.

The emptying time of the infant's stomach varies from one to four hours. Thus there is considerable individual variation in the desire for food, even in the same infant at different times of the day, and ideally the feeding schedule should be planned accordingly. With such a plan of "self-regulation" irregularity in the intervals between feedings and in the amounts taken per feeding can be expected the first few weeks, but by the end of the first month over 90 per cent of infants will have established a fairly definite schedule.

The advantages to the infant in supplying his needs as they are expressed are tremendous: he is not immediately forced into conflict with his environment; his physiologic needs are promptly met; he does not learn to associate prolonged discomfort as expressed by crying with feeding; he does not learn to gulp his food, or to take just a little, or to refuse some feedings completely. A reasonably regular schedule is soon established, which is essential to the family in assuming their normal activities. Such a schedule requires more understanding on the part of the parents as well as more time from the physician than does an arbitrary three- or four-hour feeding schedule.

Most healthy full term infants will want from six to ten feedings a day during the first week of life. By the time the mother's milk supply is established the majority will take enough at one feeding to satisfy them for approximately four hours; some who are smaller or whose gastric emptying time is more rapid will want food about every three hours. Consistent crying at shorter intervals should raise the question of an inadequate milk supply, mechanical difficulties associated with feeding, or discomfort from some cause other than hunger. Most infants will not awaken for the middle of the night feeding after three to six weeks of age; some may never need it. The majority will skip the late

evening feeding between four and eight months of age and will be satisfied with three major feedings per day by nine to twelve months.

In helping a mother to establish a schedule geared to the infant's needs and behavior, it is important to point out that he may cry for reasons other than hunger and that he need not be fed every time he cries; some infants are placid, some active, some irritable, and a sick one is usually apathetic about food. The habit of offering frequent small feedings or of holding and feeding to pacify all crying is to be avoided. Too much clothing, wet, tight or uncomfortable clothes, an environment that is too hot or cold, swallowed air, colic, illness or discomfort from any cause and lack of sufficient attention are the most frequent reasons other than hunger for an infant's crying. Infants who stop crying when they are picked up or held are usually not in need of food, nor are those who do not stop crying when food is offered.

After the first two or three weeks a "self-regulated" schedule for the infant need not interfere too much with the rest of the family's activities. Individual feedings or the whole day's schedule can be moved ahead or delayed sufficiently to avoid conflicts with the family mealtimes, bedtimes and other activities essential to family living.

Some mothers will not understand the goals of self-regulation by the infant, some will misinterpret the physician's instructions, and others may not have the capacity to adjust themselves to the regimen of the infant. The orderly, overanxious and compulsive type of parent will do better with a more specific outline for the infant's activities.

## BREAST FEEDING

See page 121 for composition of human and cow's milk.

**Colostrum.** The secretion of the breasts for the first two to four days after delivery is termed "colostrum." It has a deep lemon-yellow color, its reaction is alkaline, and its specific gravity is 1.040 to 1.060, in contrast to an average specific gravity of fresh breast milk of 1.030. Colostrum contains several times as much protein as does breast milk, but less carbohydrate and fat. The total amount of colostrum secreted daily is not large (10 to 40 cc.). Subsequent to the changes after the first few days of lactation from colostrum to milk, there is a further gradual transition

during the next two or three weeks until characteristic breast milk is secreted.

**Advantages of Breast Feeding.** Breast milk is not only the natural but also the ideal food for full term infants during the first few months of life. It can scarcely be said that the milk of various mammals is specific for the species in the sense that the young of one species cannot be nourished by the milk of another. There are, however, quantitative differences in the content of protein, carbohydrate, fat, minerals and vitamins in the milk of various species, and the nurslings of the various species do well on their natural milk supply. During the first three or four months of life the infant who is successfully breast-fed by a mother whose diet is quantitatively adequate and properly balanced will receive the necessary nutrients, with the exception of vitamin D and possibly of C. Though breast milk is low in iron, that stored during the latter part of fetal life will supply the requirements for the first three or four months.

The practical aspects of breast feeding are apparent. Human milk is always readily available at the proper temperature wherever the mother may be. It is always fresh and free of contaminating bacteria, and errors in preparation of formulas are avoided, so that the chances of gastrointestinal disturbances are greatly reduced.

In the past there was a much higher mortality rate among artificially fed infants than among breast-fed ones. It now appears that there may be little, if any, difference in the mortality rates of artificially fed and breast-fed infants when they receive good pediatric care. Among the lower socio-economic groups or where sanitary conditions are poor the breast-fed infant continues to have a much better chance of survival.

There are fewer and less serious feeding difficulties among breast-fed than among artificially fed infants. There is some evidence that breast-fed infants may acquire greater passive immunity than artificially fed ones. In a group of infants receiving good pediatric care Stevenson found a higher incidence of respiratory infections during the second six months of life in artificially fed than in breast-fed infants. The incidence of atopic eczema is about seven times greater in artificially fed infants.

It has been suggested that the intestinal flora of infants fed human milk provides special benefits. The stool of the breast-fed infant has a lower pH than that of an infant fed cow's milk, and the bacterial content is pre-

dominantly of the lactobacillus group in contrast to a predominance of the coliform group in artificially fed infants. György demonstrated that a strain of *L. bifidus* requires a "growth factor" contained in milk for its propagation. This factor appears to be abundant in human and rat milks, but present in only slight amounts in the milk of cows, goats and sheep.

Much has been said about the psychologic effects of breast feeding on the infant and on the mother. Certainly successful breast feeding is a satisfactory experience for both. For the mother there is the sense of accomplishment and of essentialness; however, the mother who wishes but is unable to nurse her infant need have no less a sense of affection for him. Though it has been suggested that the breast-fed infant will be emotionally more stable than the bottle-fed infant, it would seem that the latter, provided he is a "wanted baby," would receive adequate protection and affection from the mother. In a world that needs stability there seems to be no justification for projecting a new "fear neurosis." The theory that emotional instability is likely to be an aftermath of bottle feeding requires confirmation which is not available, and until it is, it should be emphasized that security and affection can be given to a bottle-fed infant.

**Disadvantages and Contraindications.** For the average, healthy, full term infant there are no disadvantages to breast feeding, provided the mother's milk supply is ample and her diet contains sufficient amounts of protein and vitamins. Infrequently, allergens to which the infant is sensitized may be conveyed in the milk. In such instances an attempt should be made to find the specific allergen and to remove it from the mother's diet; the presence of such allergens rarely becomes a valid reason for weaning the baby.

The infant who is too weak to nurse because of prematurity, general debility or illness, or unable because of a cleft lip or palate, should receive milk, when available, that has been pumped or expressed from the breasts.

From the standpoint of the mother there are temporary or permanent contraindications to breast feeding. Fissuring or cracking of the nipples is an indication for temporary cessation of nursing when the use of a nipple shield is unsatisfactory. Mastitis necessitates discontinuance of nursing, although, when treatment is rapidly effective, breast feeding may be resumed after several days. Acute illness in the mother may be considered a contraindication to breast feeding if the in-

infant does not have the same infection; otherwise there is no need for cessation of nursing unless the condition of either makes it mandatory. When the infant is not affected and the mother's condition permits, the breasts should be emptied, and the milk may be sterilized and given to the infant.

Severe disturbances such as septicemia, nephritis, eclampsia, severe hemorrhage, active tuberculosis, typhoid fever or malaria are permanent contraindications to nursing, as are chronic poor nutrition, debility, epilepsy, insanity, neurosis, postpartum psychosis and regnancy.

When the mother is repulsed by the thought of nursing her infant, it is probably wise to avoid an issue which might further disturb the mother-infant relationship.

The onset of menstruation is not a contraindication to continued nursing, although there may be changes reflected by different behavior of mother or baby which necessitate reassurance that they are temporary.

Erythroblastosis fetalis is not a contraindication to breast feeding, if the infant's general condition warrants it, since antibodies in the mother's milk are inactivated in the intestinal tract and do not contribute to further hemolysis of the infant's red blood cells.

**Preparation of the Prospective Mother.** Despite the fact that breast milk is the natural food for infants, many receive little or none of it. Some mothers are not good milk producers and are unable to provide an amount sufficient to justify even partial feeding of their infants (combined breast and supplemental milk feedings). Great improvement in the quality of artificial feeding has been a large factor in the decreased incidence of breast feeding; "emancipation of women" and the tempo of modern living are also contributing elements. Some groups do not consider breast feeding a socially acceptable procedure. Employment of women outside the home necessitates artificial feeding in many instances. Many mothers are reluctant to nurse their infants because of the limitation on their social activities or because of the fear of loss of physical attractiveness, especially through gain in weight and loss of breast tone.

To permit the mother greater freedom of activity outside the home, a daily bottle of formula can be substituted for one of the breast feedings by the time she is ready to resume her normal activity. Actually, there are advantages in such an arrangement. The psychologic effect on the mother is perhaps the most important, but there is also training

of the baby in feeding from the bottle so that weaning at the usual time is facilitated. The mother may be reassured that she need not gain or lose weight if her diet is adequate. Both mother and father should be reassured that breast tone may be preserved by the use of a properly fitted brassiere to support the breasts, especially before delivery and during the nursing period.

The advantages of breast feeding must be explained to the prospective mother early in her pregnancy. It might even be pointed out during puberty or before that the primary physiologic function of a woman's breasts is to feed her children. Physical factors consist in establishing and maintaining a healthy status by properly balanced rest and exercise, freedom from worry, early and adequate treatment of any intercurrent disease and adequate nutrition. Nutritional deficiencies are one of the causes of premature birth and of increased infantile morbidity, and are possibly contributory factors to infantile mortality and to inadequate lactation.

There does not appear to be any advantage in the use of the so-called hardening processes designed to toughen the nipples. Such procedures may increase the likelihood of cracking or fissuring. Retracted nipples may be benefited by daily manual or breast pump traction during the latter weeks of pregnancy, but true inverted nipples are not helped.

#### ESTABLISHMENT AND MAINTENANCE OF THE MILK SUPPLY

**Psychologic Factors.** Attention to the details of maternal hygiene are paramount. No factor is more important than a happy, care-free state of mind; worry and unhappiness are the most effective means for decreasing or abolishing breast secretion.

Mothers worry that their babies are abnormal when they cry, when they are drowsy, when they sneeze or eructate a mouthful of milk. Mothers are upset about any suggestion that their milk may be lacking in quantity or quality. They are disturbed at the thin appearance of colostrum, at tenderness of the nipples and at the fullness of the breasts on the fifth day. Many mothers cannot feel comfortable trying to nurse in an open ward or even with one person in the room. Most mothers worry about what is going on at home while they are hospitalized and about what is going to happen when they arrive home. An alert nurse or physician is conscious of these worries, particularly if the baby is a first-born, and by tactful reassurance and ex-

planation can help to prevent or minimize worry and thus contribute to successful breast feeding.

**Fatigue.** Avoidance of fatigue is important, but the mother should have sufficient exercise to promote a sense of physical well-being.

**Diet.** The diet should contain enough calories to compensate for those contained in the secreted milk as well as those required for its production. A diet adequate to maintain weight and relatively high in protein, fluid, vitamins and minerals will suffice. However, the mother should have the benefit of instruction in the make-up of her diet. Milk is important, but should not replace other essential foods. When the mother is allergic or has an aversion to milk, 1 gm. of calcium may be added to her daily diet. The fluid intake should approximate 3 quarts daily.

There are mistaken ideas that such substances as milk, beer, oatmeal and tea are galactogenic. There is no objection to small amounts of alcoholic beverages or to smoking in moderation if they contribute to the mother's peace of mind and sense of well-being. Seldom does a particular food in the mother's diet have a disturbing influence on the breast-fed infant. Occasionally, however, some items in the maternal diet, such as certain berries, tomatoes, onions, members of the cabbage family, chocolate, spices and condiments, may cause gastric distress or loose stools in the infant. No food should be withheld from the mother's diet unless it causes distress to the infant. It is better to control the mother's constipation by inclusion in the diet of raw and cooked fruits and vegetables, whole wheat bread and an adequate amount of water than by the use of laxatives. Certain drugs, such as the barbiturates, bromides, iodides, salicylates, opium, atropine, sulfonamides and cascara, may be transmitted through the milk and exert an effect on the infant.

**Hygiene.** The nipples should be washed with water before and after each nursing and once or twice a day with soap and water. As a rule, no other care is needed; the important factor is to keep the nipple dry. The use of boric acid should be avoided. Care should be taken to prevent irritation and infection of the nipples by prolonged initial nursing, maceration from wetness of the nipple, irritation of clothing, or difficult nursing associated with engorged or overdistended breasts. Serious difficulties can usually be avoided by taking the infant off an affected breast temporarily and expressing the milk manually.

Occasionally nipple shields may be of help. The infant should be returned to breast feeding as soon as the nipple has healed.

A properly fitted brassiere should be worn day and night. A piece of clean cloth may be placed inside the brassiere to absorb any milk which leaks out.

*Manual expression of breast milk* is achieved by two movements. The first is compression of the whole breast between the hands, starting at the base and continuing toward the areola. Firm pressure is maintained throughout the movement, which is repeated several times. The purpose is to impel milk to the lacteal sinuses. The second movement should empty the sinuses. The breast is supported with one hand while the tissue just behind the areola is repeatedly compressed between the thumb and first finger of the other hand. The direction of the force is backwards toward the center of the breast rather than toward the nipple. The fingers are not moved from this initial position, nor is the skin rubbed over the breast tissue. The procedure should not be painful even though the nipples are sore and cracked.

**Stimulation.** It is essential in establishing an adequate milk supply for the breasts to be stimulated. The only known satisfactory stimulus to the secretion of human milk is regular and complete emptying of the breasts. There are many reasons for incomplete nursing, but the principal ones are weakness of the infant and failure of initiation of a natural hunger cycle. When the breasts are not emptied completely by the infant during the early days of nursing, they should be emptied regularly by artificial means. This is sometimes necessary on the fifth day to relieve overdistention of the breast so that the infant is able to grasp the mother's nipple. A hand breast pump or a water suction pump may be used, or the mother may be taught manual expression. Every effort should be directed toward the establishment of natural, vigorous nursing. This is accomplished by letting the infant empty the breasts frequently during the time when colostrum is being formed. The infant should be allowed to nurse when he is hungry whether or not there appears to be any milk. It is probably unimportant whether he be put to breast shortly after delivery or after a lapse of twenty-four hours, but early acquaintance with his mother's breast is much more important than prelacteal feedings.

Centralized nurseries in busy maternity services necessitate a fairly rigid schedule of infant feeding. Infants seem to do fairly well

Under such circumstances if they are allowed to nurse twice or three times during the second day and every four hours thereafter. Sterile water or 5 per cent glucose solution may be offered after nursing if they still desire fluid. Nature never intended babies to be fed on an arbitrary schedule, and much can be said for the "rooming-in" plan. Breast feeding is more successfully established and maintained when the baby is allowed to nurse when he is ready than at prescribed times.

Though lactogenic hormones have been effective in certain mammals, there is no evidence that they are effective in the stimulation of breast secretion in the human being.

The first two weeks of the neonatal period is the crucial time for the establishment of breast feeding. Too much emphasis is put on daily weight gains. If early supplemental milk feedings are given to achieve this false goal, attempts at successful breast feeding are doomed to failure, since it is usually easier for the infant to get milk from a bottle than from the breast.

Supplemental milk should never be given before the fifth day and rarely before the end of the first week. An exception may be made on the day the mother is discharged from the hospital, particularly if her confinement is limited to four or five days. By that time lactation may not be well established, and the excitement of going home may not be conducive to an initial successful nursing experience there. A wise doctor may foresee this experience and supply the mother with enough isocaloric formula for complementary feedings for the rest of the day and evening, thus avoiding a discouraging situation that might well prejudice the success of further nursing. By his pointing out the effect that such excitement and unusual activity are likely to produce, she will not be so upset when her milk supply is temporarily decreased.

#### TECHNIQUE OF BREAST FEEDING

The technical aspects of breast feeding require careful consideration. It is not unusual for breast feeding to be deemed impossible simply because the attending physician fails to recognize that the difficulties are related to the manner of feeding and not to qualitative or quantitative inadequacies of the milk.

The infant should be hungry at feeding time, dry and neither too cold nor too warm. He should be held in a comfortable, semi-sitting position for his enjoyment and for facilitation of eructation without vomiting.

The mother, too, must be comfortable and completely at ease. When she is able to be out of bed, a moderately low chair with armrest is preferable, and a low stool is advantageous for resting her foot and raising her knee on the nursing side. The baby is supported comfortably with his face close to the breast by one arm and hand while the other hand supports the breast so that the nipple is easily accessible to the infant's mouth and yet does not obstruct his nasal breathing. The baby's lips should be well out over the areola of the breast.

Success in infant feeding depends to a great extent upon the adjustments during the first few days of life. Difficulties are likely to result when attempts are made to adapt the infant to the nursing procedure rather than to try to satisfy his natural desires. If he is put at the breast when there is normal hunger crying and if his appetite is satisfied, the fundamental requirements are met. Two difficulties in this respect are the rigid adherence to clock schedules in the hospital nursery and the mechanistic manner in which many infants are handled. Most of the difficulties can be avoided by conforming to the infant's natural pattern. Aldrich emphasized the natural initial responses to hunger; his account of one of them, the rooting reflex, is so well phrased

FIG. 22. Technique of nursing. (Lyon and Wallinger: *Mitchell's Pediatrics and Pediatric Nursing*.)

that we have taken the liberty of reproducing it here.

At the time he is born, the normal infant is equipped with several reflexes, or behavior patterns, which are designed to make him a successful feeder from the breast. The most obvious of these reflexes are those concerned with the actual getting of food—rooting, sucking, swallowing, and satiety reflexes.

The *rooting reflex* is the first one of these to come into play. When a baby smells milk, he moves his head around and attempts to find its source. If one cheek is touched by a smooth object, he will turn his mouth toward that object and open it in anticipation of grasping the nipple. This obviously gives a clue as to how milk should be given to the baby. His cheek applied to his mother's breast will start him rooting with his mouth for the nipple.

I can illustrate a mistake made in this regard by telling the . . . experience of a patient in one of our best hospitals. As I was making daily rounds, she said to me: "Your nurses don't know their stuff! . . . They don't know anything about the rooting reflex. They bring my baby in, place her beside me and with their hand on the baby's cheek try to push her head around to meet the nipple. The baby, feeling the pressure of the hand, tries to turn toward the nurse's palm instead of toward my breast. A fight ensues, and usually the natural response is prevented. I always tell the girls to go out of the room; that I can handle this myself if they just lay the baby down beside me. I touch her cheek with my breast and let her do the rest." This experienced mother had learned to respect her baby's ability in these basic matters. This is a highly important lesson for anybody to learn.

Mothers should know that if the infant is not hungry, he will not search for the nipple or suck. Infants are unusually sleepy for several days, and most are not initially avid suckers. Particularly on the third day, when there has been some weight loss, mothers are anxious about infants who do not seem particularly interested in eating. It is reassuring for them to know that most healthy babies "wake up" and become good eaters on the fourth day.

The "let-down" reflex, wherein milk flows from one nipple when the baby nurses from the other, is a sign of successful nursing rather than of an abnormality and is not present in a worried mother.

Some infants will empty a breast in five minutes; others will be more leisurely and nurse well for twenty minutes. The baby should be permitted to suck until he is satisfied. Efforts to wake up a sleepy baby and to "make him" nurse by snapping his feet, pinching or shaking him are rarely successful.

At the end of the nursing period the infant should be held erect over the mother's shoulder to eructate swallowed air; often this pro-

cedure is necessary at one or more intervals during the feeding as well as five to ten minutes after the infant has been put into the crib. It is an essential procedure during the early months. When nursing is completed, the infant should be placed in the crib on his abdomen or on his right side to facilitate emptying of the stomach into the intestine and to lessen the chances of regurgitation.

**One or Both Breasts per Feeding.** After the milk supply has been well established the breasts may be alternated at successive feedings, and the baby will usually be satisfied with the amount from one side. It is important that he empty at least one breast at each feeding; otherwise it will not be stimulated to refill. If the supply seems inadequate, it is advisable to offer both breasts at each feeding, alternating the one offered first, so that it will be completely emptied at each feeding. When the secretion of milk is too great, however, both breasts may be offered at each feeding and incompletely emptied with the intent of securing a partial decrease in lactation.

**Determination of Adequacy of Breast Supply.** If the infant is satisfied at the completion of the nursing period, sleeps for three to four hours thereafter, and gains weight satisfactorily, it can be assumed that the breast supply is adequate; weighing of the infant at other than weekly to monthly intervals is neither necessary nor desirable. If, however, the infant nurses avidly and is not satisfied after completely emptying both breasts, does not go to sleep quickly, sleeps fitfully and/or awakens after an hour or two and gain in weight is not satisfactory, it is probable that the milk supply is inadequate. The extent to which the mother's breasts become filled during the intervals between nursing is an additional measure of her capacity to produce milk.

Weighing a baby before and after nursing is generally an unsatisfactory way of judging adequacy of breast supply and is fraught with danger of misinterpretation. It wrongly focuses attention on how much the baby takes at a given time (this may normally vary from a fraction of an ounce to 8 to 10 ounces in the various feedings during a twenty-four hour period) and hence causes the mother to worry and the supply to diminish. She then wishes to give him a bottle so that she can see how much he gets and know that it is enough. Before it is assumed that the mother is unable to produce sufficient milk, three factors should be considered: (1) that tech-

cal faults are not responsible for the infant's inadequate progress; (2) that there are no medial maternal factors related to diet, rest and/or psychologic disturbances; and (3) that the infant has no physical disturbance which interferes with eating or otherwise with gain in weight.

**Supplementary Feedings.** One substitute feeding a day, after the first week or two and after the mother's milk supply has been adequately established, has the advantage of permitting the mother greater freedom in her activities and of familiarizing the infant with the bottle so that weaning will be facilitated later. If a baby who is otherwise normal and healthy is getting insufficient breast milk, he could be offered additional artificial feedings either immediately after or in place of one or more breast feedings. Any of the milk formulas described under Artificial Feeding may be used and should be offered to the baby in amounts sufficient to satisfy him.

If a formula is to be given after the baby has completed a breast feeding, the bottle should be warmed and handy so that it can be offered immediately after the infant has been given an opportunity to eructate any swallowed air. The holes in the nipple should not be so large that the baby gets this portion of his food without any effort, or he will quickly abandon any efforts to suck adequately at his mother's breast.

A replacement feeding is preferably substituted for the breast when the milk supply is observed to be scantiest, usually late in the afternoon. The infant is given as much as he wants of an isocaloric formula. It is frequently accepted better from a person other than the mother, from whom he is conditioned to nurse. Combined breast and bottle feedings may be continued as long as seems practical and satisfying to the mother and the infant.

**Breast Milk from Sources Other than the Infant's Mother.** With improvements in artificial feeding the use of breast milk from other than the maternal source has decreased. Direct wet-nursing, once widely used, is now a rarity. When a wet nurse is employed, she must be known to be free of all contagious disease, especially tuberculosis and syphilis. In some maternity hospitals it is common practice to collect excess breast milk by means of an electric breast pump for the feeding of weak or sick infants. A number of the larger cities have so-called breast milk stations where breast milk is collected, pasteurized, dried or frozen and dispensed. All women who con-

tribute milk must be in good health, and supervision must be maintained to prevent contamination or dilution of the milk.

## WEANING

Weaning is usually advisable when the infant is six to nine months of age, but should be avoided, if possible, during extremely hot weather. When a bottle feeding per day has been substituted for one of the breast feedings, as suggested previously, there is no difficulty in weaning. When the infant is not acquainted with the bottle, cup feeding may be tried. Not infrequently the cup is taken as readily as the bottle, and the subsequent transfer to cup from bottle feeding is avoided. In any event, when the mother's milk supply is abundant, the process of weaning should be sufficiently gradual to avoid causing her unnecessary discomfort and to let the baby learn to accept milk from a new source. Initially, one of the breast feedings is replaced by a bottle feeding. After several days another breast feeding is replaced, and so on until the baby is entirely weaned. The total time required is governed by the status of the maternal milk supply. One breast feeding a day may be continued for several weeks, if necessary, to avoid discomfort from engorged breasts.

When weaning is necessary at an earlier age because of illness of the mother or for other reasons, or if breast secretion is no longer needed because of the death of an infant, a tight breast binder may be used and ice bags applied for a day or so. The mother's fluid intake should also be restricted.

## ARTIFICIAL FEEDING

The term "artificial feeding" is used for non-breast milk feedings during the period when the infant would naturally receive human milk. Cow's milk in the fresh whole state or in some modified form is the basis for most formulas. There are, however, a number of milk substitutes for infants hypersensitive to cow's milk.

Artificial feeding, once a complicated procedure from the standpoints of calculation and preparation, is now a rather simple one. Sterilization of the formula and refrigeration of it until used, so that bacterial contamination is avoided, have been important factors in the reduction of morbidity and mortality from gastrointestinal infections in the first year of life. Though infants can now be fed reasonably well by artificial means, and it is

often impossible to distinguish those who are breast-fed from those who are artificially fed, there are strong arguments for breast feeding during the first months of life (p. 114).

#### TECHNIQUE OF ARTIFICIAL FEEDING

In principle, this is the same as that described for breast feeding. The infant should be hungry, fully awake, comfortably warm and dry. The mother should be in a comfortable position, pleasant, unhurried and free of distractions. The baby should be held just as though he were being nursed. The bottle should not be propped, even in a "safe" holder, since this deprives the infant of the comfort and security he can get from being held. It may be dangerous, particularly to a small baby, to leave him unattended even momentarily with a bottle in his mouth. The bottle should be held so that milk, not air, is channelled into the nipple.

The bottle of milk should be warmed to body temperature; it may be tested by dropping milk on the wrist. The sterile nipple should be applied without contaminating it. The holes of the nipple should be of such a size that the milk will drop slowly.

Especially during the first six or seven months of life, the eructation of swallowed air during feeding is important to avoid discomfort as well as regurgitation. Eructation is facilitated by holding the infant upright over the shoulder with or without gently rubbing or patting the back. A few relieve themselves best after being replaced in the crib. Lying on the abdomen or right side facilitates this procedure and makes it easier for the stomach to empty into the intestine. All babies will at times regurgitate or "spit up" a small amount of milk after feeding, a fact which the mother should know. It occurs more often in artificially fed than in breast-fed infants. Aspiration of this milk is less likely if the infant lies on his side or abdomen, rather than on his back.

A feeding may require from five to twenty-five minutes, depending on the vigor and the age of the infant. Since the appetite varies from feeding to feeding, each bottle should contain more than the average amount taken per feeding. In no instance should the baby be urged to take more than he desires. The excess milk should be discarded, and the bottle and nipple rinsed with cool water.

#### COMPARISON OF HUMAN AND COW'S MILK

Average values for the various constituents of human milk and whole fresh and evaporated

cow's milk are listed in Table 22. Human milk and cow's milk differ during the various stages of lactation, and there are some differences between the milks of individual women as well as of cattle. The initial secretion of each is known as colostrum, which is described on page 113. For women whose diets are adequate in protein, vitamins, minerals and total calories, the differences in the milks are insignificant.

**Water.** The relative amounts of water and solids in human and cow's milk are about the same, the water content of each being about 87 to 87.5 per cent, with a specific gravity in the range of 1.030 to 1.032.

**Calories.** Though there are slight variations in the energy value of each milk, for practical purposes each may be assumed to be equivalent to 20 calories per ounce.

**Protein.** There are both qualitative and quantitative differences between the proteins of the two milks. Human milk contains only 1 to 1.5 per cent protein, in contrast to about 3.5 per cent in cow's milk. The principal qualitative differences are the relative amounts of lactalbumin and casein. In human milk the protein consists of approximately 6 per cent lactalbumin and 40 per cent casein whereas in cow's milk there is about 85 per cent casein and 15 per cent lactalbumin. Each milk contains small amounts of other proteins, including lactoglobulin. The proteins of the two milks are essentially equivalent for infant nutrition.

**Carbohydrate.** The sugars of the two milks differ only quantitatively, both being lactose. Human milk contains from 6.5 to 7 per cent, and cow's milk about 4.5 per cent.

**Fat.** The fat content of milk is more variable than any other constituent. The average content of each is about 3.5 per cent. The amount of fat in human milk varies somewhat with the maternal diet. The fat content of the latter portion of milk obtained at a single nursing is higher than that of the first portion.

The milk of different breeds of cattle varies in its fat content. Most market milk in urban areas, however, is pooled and the fat content adjusted to a standard level, generally from 3.25 to 4 per cent. As a rule, milks with the lower fat content are preferable for the feeding of infants.

There are qualitative differences between the fats of human and cow's milks. The fats of each are composed principally of the triglycerides, olein, palmitin and stearin. Human milk, however, contains relatively larger

quantities of the more readily absorbed olein. The volatile fatty acids (butyric, capric, propionic and caprylic) account for only about 5 per cent of the fat of human milk, in contrast to about 27 per cent of that of cow's milk. Though the normal full term infant has no difficulty in digesting the fat of cow's milk, the premature or debilitated infant may have difficulties. In such instances it is well to keep the fat content of the milk formula relatively low or substitute a more readily assimilated fat such as olive oil.

**Minerals.** The total mineral content of human milk (0.15 to 0.25 per cent) is considerably less than that of cow's milk (0.7 to 0.75 per cent). With the exception of iron and copper, cow's milk contains considerably more of all the minerals. Neither milk contains an adequate amount of iron; the deficiency is compensated for in the first four

months or so of life by fetal stored iron. Although the need for calcium and phosphorus is relatively great during the periods of rapid growth, adequate balances are maintained on breast milk in spite of its comparatively low content of these minerals.

**Vitamins.** The vitamin content of each milk varies with the maternal intake. Each has relatively large amounts of vitamin A and small amounts of D. Human milk contains more C except when there is a deficiency in the maternal intake of vitamin C-containing foods. The maximum secretion of vitamin C is one and a half hours after ingestion. Cow's milk contains more thiamine and riboflavin than human milk and about an equal quantity of niacin. It is assumed that each milk contains adequate amounts of vitamin A and inadequate amounts of vitamins C and D for the nutritional needs of infants and adequate

Table 22. Comparison of Human Milk with Cow's Milk (Whole and Evaporated)

	Human Milk	Cow's Milk	
	(Per Cent)	Whole (Per Cent)	Evaporated (Per Cent)
Water.....	87.0-88.0	83.0-88.0	73.0-74.0

amounts of vitamin B complex for the first few months of life before cereal and other foods are started.

**Bacterial Content.** Human milk is essentially free from bacterial contamination. When there is mastitis, pathogenic organisms in significant numbers may gain access to the milk. Both tubercle bacilli and typhoid bacilli may be found at times in the milk of women infected with these organisms. Cow's milk is regularly contaminated, but in most instances the bacteria are not especially harmful for man. Cow's milk, however, is a good vehicle and even a culture medium for pathogenic bacteria, and many infections are milk-borne. Such infections include streptococcal pharyngitis, scarlet fever, diphtheria, typhoid fever, salmonellosis, tuberculosis and brucellosis. Furthermore, certain bacteria which may not have any disturbing effect upon older children or adults may cause diarrheal disturbances in infants. For this reason, in most cities pasteurization of all market milk, even certified, is required. In addition, boiling of the milk immediately before mixing the infant's formula or terminal sterilization is advisable.

**Digestibility.** The emptying time of the stomach is more rapid for human than for cow's milk. This is apparently due to the higher buffer content of cow's milk, which requires more acid for its digestion, and to the larger amount of casein, which is responsible for the production of large tough curds in the stomach. By contrast, the curd of breast milk is fine and flocculent and readily broken down in the stomach. The curd of cow's milk is somewhat reduced in size by boiling and is made considerably less tough and much smaller by the heating required in the production of evaporated milk, by the addition of acid or alkali or by homogenization. The fat of cow's milk is less readily digested than that of breast milk.

#### FORMS OF COW'S MILK USED IN FORMULAS

**Raw Milk.** Most urban centers forbid the sale of milk in the raw state, even of unpasteurized certified milk. Raw milk is not advised for infant feeding because it is slowly digested, forms large curds in the stomach and is likely to be contaminated with pathogenic organisms.

**Pasteurized Milk.** Pasteurization destroys pathogenic bacteria and alters the casein to some extent, so that smaller and less tough curds are produced in the stomach. Pasteurization is accomplished by heating milk at a

specific temperature for a specific length of time, e.g., at 143° F. for thirty minutes. Standards for the bacterial content of pasteurized milk vary in different cities, being as high as 50,000 nonpathogenic bacteria per cubic centimeter; averages in many cities, however, are as low as 5000 to 10,000 bacteria. Pasteurized milk should be boiled when used for infant feeding. If allowed to stand in the refrigerator for as long as forty-eight hours, it can show a significant increase in the number of bacteria.

**Certified Milk.** Milk marketed under this designation must meet rigid requirements. The cattle must be examined at regular intervals for all types of illness, including tuberculosis and brucellosis. The barns must be constructed so that adequate cleaning is possible and must be screened. The milkers are also examined for disease at regular intervals. Each step in handling of the milk is guarded to avoid bacterial contamination. Immediately after milking, the milk is cooled to 45° F. and maintained at this temperature until delivery. Bacterial requirements vary, but not more than 10,000 bacteria per cubic centimeter are permitted in any city. Many cities require certified milk to be pasteurized. Boiling it for infant feeding is advisable in order to increase its digestibility.

**Homogenized Milk.** The processing of milk so that the fat globules are broken into minute particles is termed "homogenization." By one method, milk is forced through minute openings in a metal plate under high pressure. Owing to the decrease in size and the dispersion of the fat molecules, the cream does not separate. The principal advantage of homogenized milk lies in the smaller and less tough curd produced in the stomach.

**Evaporated Milk.** Evaporated milk has numerous advantages in addition to its almost universal availability. In the unopened can it will keep for months without refrigeration. The casein is altered so that the curd produced in the stomach is softer and smaller than that of boiled whole milk. The effect of homogenization on the fat molecules also contributes to the smaller curd formation. The lactalbumin appears to be less allergenic than that of fresh milk. The sugar is unchanged. It can be fed when necessary in higher concentrations than whole milk formulas.

The standard can contains 14.5 ounces avoirdupois or 13 fluidounces. In each fluidounce there are about 44 calories; in practice it is generally figured as 40 calories. Since more than one can of evaporated milk is

dom used for a daily feeding, whether it is uted with an equal quantity of water (13 nces) or reconstructed at a ratio of 1:1.2 5½ ounces), it is equivalent to only about ounces of whole milk. Vitamin D is added most evaporated milks in an amount so at each reconstructed quart contains 400 U.

**Condensed Milk.** About 45 per cent of ne sugar has been added in sweetened condensed milk, and it is impossible to dilute is without having a mixture disproportionately high in sugar and low in fat and otein. Although it is readily digestible, it is no use in infant feeding for more than ort periods when a high caloric diet is esired.

**Dried Milk. Whole milk.** Standard regulations govern the production of dried milk. he fat content of fluid milk is adjusted to 5 per cent, and the milk is evaporated with treme rapidity to powder form. Reconstructed dried milk has most of the advantages evaporated milk. Dried milk has its great usefulness in the feeding of infants in stitutions. It has limited keeping qualities hen exposed to air. In reconstructing dried milk to its original fluid state, 1 ounce by eight (3½ packed level tablespoonfuls) is added to 7 ounces of water.

**Dried skimmed milk.** Available with varying percentages of fat content up to about 1.5 er cent, dried skimmed milk has limited usefulness: (1) for infants with fat intolerance, (2) during convalescence from diarrheal diseases; and (3) for diets high in protein and low in fat for premature infants. n the reconstruction of dried skimmed milk, ounce by weight is added to 9 ounces of water.

**Acid Milk.** So-called acid milks are prepared by addition of acid or by fermentation by bacterial action. Such milks require less hydrochloric acid from the gastric juice for digestion. The casein is altered so that a smaller and less tough curd is formed in the stomach. These factors appear to be advantageous in the feeding of infants with digestive disturbances and of those convalescing from diarrheal disturbances. Acid milk does not appear to have decided advantages for healthy infants.

**Lactic acid milk.** Lactic acid, U.S.P. is added to previously boiled and cooled cow's milk formulas; the amount required varies with the fat content, those with the higher concentrations requiring more acid. Milks

containing 3.5 to 4 per cent fat require about 1½ fluid drams (6 cc.) to the quart. Reconstructed evaporated milk requires about the same amount. The acid is added drop by drop to the cooled milk formula with constant stirring with a wooden spoon to avoid curd formation. There are several commercial preparations of dried lactic acid whole and skimmed milk.

**Fermented milk.** This milk also contains lactic acid. Buttermilk, once widely used in infant feeding, is now rarely used, and most fermented milks are prepared by culture with a lactic acid-producing organism (*Lactobacillus acidophilus* and *L. bulgaricus*).

**Vitamin D Milks.** In addition to the wide availability of fortified evaporated milk (400 I.U. per reconstructed quart), fortified whole milk containing 400 I.U. of vitamin D per quart may be had in most cities. Homogenization of vitamin D milk is a distinct advantage, since it ensures even distribution of the fat which contains the vitamin D.

#### OTHER MILKS USED IN FORMULAS

**Goat's Milk.** The composition of goat's milk is similar to that of cow's milk: fat, 4 per cent; carbohydrate, 4.5 per cent; protein, 4 per cent. The curd tension of goat's milk is less than that of cow's milk. The goat seldom contracts tuberculosis, but is especially susceptible to brucellosis. In some countries goat's milk is widely used for the feeding of infants, but in this country is used chiefly for infants allergic to cow's milk. Evaporated goat's milk is available commercially. Fresh goat's milk should be boiled before use.

**Prepared Milks.** Table 23 lists the varieties of milks and milk substitutes available for infant feeding. Many of the commercially prepared ones require only the addition of water to make them ready for use. Those which have a relatively low fat and high protein content may be used satisfactorily for premature (p. 309) and debilitated infants, and for infants convalescing from diarrheal disease.

**Milk protein.** Powdered protein is used chiefly for increasing the protein content of dilute skimmed milk or other formulas for feeding during diarrheal conditions, or to premature or debilitated infants.

**Milk Substitutes and Hypoallergenic Milks.** There are a number of milks and milk substitutes for infants allergic to cow's milk. These include goat's milk, a preparation in which the protein is supplied by an amino

acid mixture (casein hydrolysate), and non-milk foods in which the protein is derived from soy beans.

FORMULAS

Most methods for calculating milk formulas result in somewhat similar combinations of milk, water and sugar. No method stands out as definitely superior. In general, there has been increasing simplification in the construction of formulas. Some clinicians feel that the healthy infant's digestive capacity is adequate to handle such a variety of formulas, and that too much attention is paid to this aspect of infant feeding.

One result of an indifferent attitude toward the details of infant feeding is inadequate teaching of medical students, who thus have an insufficient background of the principles involved. Unless the student has a concept of the infant's nutritional requirements, of how they can be supplied, and of average eating habits at the various ages, he cannot expect to guide the mother in the establishment of a "natural regimen" for her infant. What follows represents the author's teaching to medical students. The student should realize that whatever method is used, the resultant formula is to be considered only a starting one.

Subsequent modifications must be made on the basis of the individual infant's response as determined by satisfaction of hunger, character of stools and satisfactory growth response.

The formula consists of milk, water and sugar. Some modification of the milk which results in smaller curd formation in the stomach is desirable and is achieved to some extent by boiling raw milk and to a greater extent by boiling previously pasteurized milk. Homogenization and evaporation alter milk in such a way that still smaller and less tough curd formation results. The addition of acids or alkalis has a similar effect. The choice of milk depends somewhat upon available supplies and upon individual preferences.

Caloric Requirements (see also p. 98). The average caloric requirements of full term infants are about 50 to 55 calories per pound, or 110 to 120 calories per kilogram of body weight, during the first few months of life; and about 45 calories per pound, or 100 calories per kilogram (or slightly less), by one year of age; individual variations are significant. As a general rule the formula should contain approximately 20 calories per ounce.

Fluid Requirements (see also p. 97). Though there is a lack of specific data, fluid

requirements are high during infancy. During the first six months of life they range from 2 to 3 ounces per pound, or 130 to 190 cc. per kilogram of body weight, per day. The requirements are relatively high during hot weather. As a rule the infant will regulate his own fluid intake, provided adequate amounts are offered. Most of the fluid requirement is in the formula, but some is supplied in orange juice and other foods and by water between feedings.

**Number of Feedings Daily** (see also p. 113). The number of feedings required per day decreases throughout the first year, so that by one year of age most infants are satisfied with three meals a day. The interval between feedings differs considerably among infants, but, in general, ranges from three to five hours during the first year of life, with an average of four hours for full term healthy infants. Small and weak infants may desire more frequent feedings at two to three hour intervals. For the first month or two, feedings are taken throughout the twenty-four hour period, but after this the infant will usually sleep from 10 or 12 p.m. to 6 or 7 a.m. Omission of the late evening feeding (10 to 12 p.m.) varies from the third to the eighth month.

**Table 24. Average Number of Feedings per 24 Hours**

Age	Average Number of Feedings in 24 Hours
Birth-1 week . . . . .	6-10
1 week-1 month . . . . .	6-8
1-3 months . . . . .	5-6
3-7 months . . . . .	4-5
4-9 months . . . . .	3-4
8-12 months . . . . .	3

**Quantity of Formula per Feeding.** Although the quantity taken at a feeding will vary with different infants of the same age and with the same infant at different feedings, it is necessary to know the average amounts taken at various ages. It is good practice to put more in each bottle than the infant is expected to take. A general rule for estimation of the quantity of the individual feeding to be offered during the first half year of life is to add the numeral 3 to the age in months. Estimates which more nearly reflect the average infant's intake are shown above. These "rules of thumb" are at best guides, and each infant must be given the major responsibility in determining the quantity of his intake. Rarely will an infant want to take more than 7 or 8 ounces of milk at one feed-

ing if his caloric and nutritional needs adequately supplied by other foods.

Age	Average Quantity Taken in Individual Feedings
1st and 2d weeks . . . . .	2-3 ounces
3 weeks-2 months . . . . .	4-5 ounces
2-3 months . . . . .	5-6 ounces
3-4 months . . . . .	6-7 ounces
5-12 months . . . . .	7-8 ounces

**Quantity of Milk.** The amount of whole milk usually taken daily in the first months of life varies from  $1\frac{3}{4}$  to 2 ounces per pound of body weight (evaporated milk approximately 1 ounce per pound). The relative requirements are somewhat less in the first two weeks than in the succeeding five six months. Subsequently milk, though of great value, has a decreasing importance in total nutritional requirements.

Rarely is it necessary to use more than a can (13 fluid ounces) of evaporated milk or a quart of whole milk per day. By the time the infant is taking these quantities, other foods will be added to the diet in increasing amounts.

**Water.** It is common practice to dilute cow's milk with water for the feeding of infants during the first few months of life. It has been demonstrated, however, that, with reasonable environmental temperature and humidity, infants will tolerate undiluted cow's milk or fully reconstructed evaporated milk after the first few days of life. There is a tendency with such feedings for a moderate elevation of the plasma nonprotein nitrogen level. With high environmental temperature or with vomiting or diarrhea such concentrations are higher. It would seem to be good judgment to add water and sugar to milk for infants up to four to six months of age to reduce the renal solute load so far as proteins and minerals are concerned. In the two weeks or so after birth, dilution of cow's milk should result in less chance of tetany by a reduction in the amount of phosphorus to be excreted. During periods of high environmental temperature, water should be offered between milk feedings, and additional water is needed when there are unusual losses as with vomiting or diarrhea.

**Sugar.** A number of sugars are used in infant feeding, and all seem to be satisfactory. Theoretically, it might seem that lactose, the sugar of milk, would be the one of choice; however, it appears to have no advantage over the others and may even cause an increased amount of flatulence owing to

greater degree of fermentation. Cane sugar has advantages of universal availability and low cost. Its only apparent disadvantage is a greater sweetness than the others. There are a number of dextrin-maltose preparations, several of which enjoy wide popularity. Their principal advantages are a slower rate of digestion and absorption and a less sweet taste. Honey is also used, but has no particular advantages. There are several rules for estimating the quantity of sugar. In our Clinic  $\frac{1}{2}$  ounce is added to the daily formula during the first week or so of life, then 1 ounce until about four or six months, when it is discontinued, usually in two equal steps at an interval of a week or so.

Table 25. Household Measures of Some Commonly Used Sugars

Caloric value of each is 120 calories per ounce, except Dexin, 115, and Hidex, 112.

**Example of Formula Calculation.** The following are formulas for an infant three months of age weighing 11 pounds:

1. Total fluid per 24 hours ( $11 \times 2-3$ )	= 28 oz.	Cal.
2. Total whole milk ( $11 \times 1\frac{3}{4}-2$ )	= 21 oz.	420
3. Water	28 - 21 = 7 oz.	
4. Carbohydrate	1 oz.	120
(cal. per oz. - $540 \div 28 = 19+$ )		540
(cal. per lb. - $540 \div 11 = 49+$ )		

1. Total fluid per 24 hours ( $11 \times 2-3$ )	= 28 oz.	
2. Total evaporated milk ( $11 \times 1$ )	= 11 oz.	440
3. Water	(28 - 11) = 17 oz.	
4. Carbohydrate	1 oz.	120
(cal. per oz. = $560 \div 28 = 20$ )		560
(cal. per lb. = $560 \div 11 = 51$ )		

5 bottles of  $5\frac{1}{2}$  oz. each  
These formulas are examples satisfactory for the initial prescription. Subsequent adjustments of milk

and water should be made on the basis of the infant's response as measured by satiety and by the growth curve. It is not necessary to calculate the percentages of the various ingredients of formulas composed on this basis, but for those who may want it, a method of calculation is given below.\*

**Preparation of Formula. Utensils.** Several more bottles than the required number for feedings are needed for water and orange juice. Bottles should be made of heat-resistant glass, be smooth inside, and marked in ounces. A wide-mouthed bottle is preferable because it is more easily cleaned, and those with adequate protection of the nipple are preferable if the baby is to be fed away from home. There should be several more nipples than the number required for feedings. Rubber caps or a plastic such as Pliofilm held in place by cardboard retainers may be used as bottle covers. The graduate should be made of heat-resistant glass and marked in ounces. A saucepan for heating and mixing the formula, a container for nipples, a glass funnel if narrow-mouthed bottles are used, a large kettle or special bottle sterilizer, a measuring spoon, a can opener, a knife, a standard tablespoon and a strainer complete the list of utensils.

**CLEANSING OF UTENSILS.** All utensils required for the mixing and storing of the formula should be sterilized by boiling for five to ten minutes. The rubber nipples and caps should not be boiled more than five minutes. After each feeding the bottle and nipple should be thoroughly flushed and the bottle filled with water until washed with water and a detergent.

**Method.** The hands should be thoroughly scrubbed and the sterilized bottles and utensils arranged on a clean table. If whole milk is used, the bottle is turned so that the contents are mixed, and the top is washed with hot water before the cap is removed. The water for the formula (it is necessary to allow for a slight loss in boiling) is brought to the boiling point in a saucepan; the amount of whole milk ordered is added; and the whole is boiled for five minutes. Constant stirring is necessary. The sugar is added while the milk is still warm.

If evaporated milk is used, the top of the can is washed with soap and hot water, rinsed with hot water, and two holes punctured in it. The water for the formula is boiled for five minutes, and the evaporated milk and sugar are added to it. No further boiling is necessary.

The freshly prepared and sterile formula is poured in appropriate amounts into sterilized nursing bottles. The bottles are capped by aseptic technique and stored in the refrigerator until time for the feedings.

**Terminal Sterilization.** This method has practical advantages and does not require presterilization of bottles or utensils. The formula is poured into clean nursing bottles, and the nipples are applied. The nipples are then loosely covered with glass, metal or paper caps and placed in a container, with a rack on

the bottom and tall enough to prevent the bottles from touching the lid. The container is filled with water to about the midpoint of the bottles, covered and placed over a moderate flame. The water is allowed to boil gently for twenty-five minutes. The bottles are then removed with tongs and placed in a container of cold water for ten minutes. The caps are then tightened and the bottles stored in a refrigerator.

**Whole milk.** Whole milk or a reconstructed evaporated milk without added carbohydrate may be substituted for the formula when the infant is four to six months of age. Subsequently most infants will take one and a half pints to a quart of milk a day. There is no advantage in the ingestion of more, and there is the possible disadvantage that other essential foods may be displaced. Some of the milk may be incorporated in the cereal and in the preparation of such foods as custards, soups and sauces.

## OTHER FOODS

**Vitamins.** The diets of breast-fed and artificially fed babies should be supplemented from early in the neonatal period by vitamins C and D and possibly by vitamin A.

Orange and other citrus fruit juices are natural sources of vitamin C, but, since many young infants do not seem to tolerate them in amounts large enough to supply an adequate vitamin intake, it is safer not to depend on them initially. Ascorbic acid (25 to 50 mg.) in an ounce or less of boiled water (cooled before adding the acid) or in a concentrated preparation containing vitamins A and D may be used. During the second month of life orange juice diluted with water may be offered; when at least 2 ounces of fresh, frozen or canned orange juice (or equivalent amounts of other sources of vitamin C) are taken daily, the ascorbic acid may be discontinued.

Vitamin D should be started early in the neonatal period with a daily intake of approximately 800 to 1000 I.U. A number of preparations are available which in recommended doses contain this amount of vitamin D, 50 mg. of ascorbic acid and 3000 to 5000 I.U. of vitamin A. Concentrates in water-miscible vehicles are desirable to avoid aspiration of oil. Supplemental vitamin D is needed throughout the period of growth.

**"Solid" Foods.** Which of the so-called solid foods is offered first is largely a matter of individual preference, less often of the individual infant's needs. Cereal is an excellent food to offer the baby who has a large appetite early in life and is not satisfied with the calories provided by his intake of milk.

Fruits, especially bananas and pureed prunes and apricots, are usually well-tolerated and liked and may be offered first, particularly infants whose stools tend to be formed and solid and for whom a mild softening effect is desirable. Egg yolk or strained meats provide a well-tolerated source of iron. There is little evidence that the addition of any of the foods to the normal infant's diet before three or four months of age contributes in any significant way to his well-being.

Any new food should be offered initially once a day in small amounts (1 to 2 teaspoonsful). A demitasse spoon that easily fits the baby's mouth may be used. New foods are generally best accepted if fairly thin or diluted. The food is frequently pushed out rather than back by the tongue, and the fact that it is "spit out" means that the baby does not yet know how to swallow efficiently, rather than that the food does not agree with him or that he does not like it. It is important that the reaction be explained so that it is not misinterpreted by mothers. It is usually wise to offer the same food daily until the baby becomes accustomed to it and not to introduce new foods oftener than every week or two.

The feeding at which these foods are offered is not particularly important. They should be given when the baby is especially hungry and when they logically fit into the daily schedule. Some infants prefer the solid foods before milk; some take them better afterwards. There is no reason for persisting with or forcing a particular food that is definitely disliked. Most infants have the potential to enjoy eating, and a positive attitude toward it should be maintained. The family dislikes and prejudices for particular foods are contagious and should not be evidenced before the infant. The physician should avoid prescribing a definite amount of a given food lest the mother too literally interpret the suggestion. The infant's appetite is the best index of the proper amount, and respect for his wishes will avoid many problems.

**Cereal.** The various precooked cereals on the market provide in a convenient form a variety of grains excellent for infants. Most contain iron and factors of the vitamin complex. They are easily prepared by adding to boiled milk or formula.

**Fruits.** Strained or pureed cooked fruits furnish minerals and some water-soluble vitamins and usually have a mild laxative effect. Raw ripe banana is readily digested and enjoyed by most babies. It should be mashed with a fork. Many infants who are slow in accepting new foods seem to prefer fruits.

**Vegetables.** The various "colored" vegetables are moderately good sources of iron and other minerals and of the vitamins of the B complex. They may be freshly cooked and strained, but the commercially prepared vegetables are preferred by many mothers because of their convenience. "Colored" vegetables are usually added to the diet midway during the infant's first year.

**Meats, eggs and starchy foods.** These foods are usually introduced during the second and sixth months of life, although some physicians offer egg yolk and meat at an earlier age. The yolk of the egg is used initially and preferably hard-cooked and then added to cereal or other food. As with all new foods, a small amount (pea-sized) is offered at first with gradual increases up to a whole yolk daily. Egg white should be introduced with equal caution to minimize the possibility of allergic manifestations.

Meat is an excellent source of protein as well as of iron and vitamins. Ground fresh beef or liver or the strained canned meats may be used initially. They are easily digested by most babies. Meats seem to be more readily accepted when mixed with another food.

The commercial "soups" and meat and vegetable mixtures are relatively high in carbohydrate and are not to be considered optimal sources of iron or protein. Many home-prepared soups are bulky out of proportion to their food value, and much of the vitamin content is frequently lost by overcooking.

Potatoes, rice, spaghetti, bread and similar starchy foods have principally a caloric value. As a rule they are not included in the infant's diet until the more essential foods mentioned above are being taken regularly. Baked potato, mashed with milk and butter, is a favorite. Zwieback, toast or graham crackers may be offered to the infant when he shows an interest in "gumming" on coarser foods (usually about seven or eight months of age). It is with such foods that he learns to chew and to feed himself.

**Desserts.** Puddings, junkets and custards are good foods for older infants, particularly if they temporarily prefer milk in that form. If, however, such foods are given as a bribe or reward or only after other foods have been finished, a poor eating habit will be established. Sweet foods should be offered as casually as the rest of the meal and at any place in the meal that the child desires.

## FIRST-YEAR FEEDING PATTERN AND PROBLEMS

**Recapitulation.** The value and methods of establishing a fairly regular yet flexible feeding schedule have been discussed. The importance of fitting the schedule to the individual infant's requirements and of adjusting it as his needs change has been emphasized. The volume and frequency of milk feedings is best determined by the infant himself. If breast milk is not available, an adequate substitute is found in isocaloric formulas of cow's milk, water and carbohydrate. Attention to the technical details of feeding both at breast and by bottle is necessary to avoid early feeding problems. Both breast-fed and bottle-fed babies need supplements of vitamins A, C and D.

Cereal, strained fruits and vegetables and sometimes egg yolk or meat are added to the diet one at a time and initially in small amounts during the second three months of life. By about six months of age most infants are taking foods by spoon in addition to milk three times a day, with citrus fruit juice at a convenient time in between. Many will also desire milk in the early morning, and some in the late evening. During the second six months babies become less demanding of immediate satisfaction of hunger, and intervals between feedings are lengthened until a pattern of three meals a day is established. Whole egg, meats and starchy foods are added to the diet, and milk is given as whole cow's milk. Variation in the amounts of either solid foods or milk taken at various meals should be expected. Often there are cyclic patterns of exaggerated likes or dislikes for solids, liquids or particular foods. Foods should never be forced; when an infant objects to a particular food, it is well to avoid it for a few weeks. Most foods will be liked, however, if conflicts over them are avoided. Good as well as bad eating habits are established early; eating should be a pleasant experience.

During the second half year of life the infant will show a readiness to chew rather than just to swallow foods. This is an indication for offering him coarser foods such as toast or crackers and to give him less finely strained fruits and vegetables. The canned chopped foods have a limited place in the transition to foods eaten by older members of the family. Vegetables should be mashed and meats ground until the chewing function is well developed. Considerable latitude in the

self-selection of foods should be allowed, but a balanced diet should always be offered.

The physician must interpret for the mother the infant's decreased desire for food during an illness. Her desire not to alter his usual feeding pattern can result in a conflict over food and mark the beginning of poor eating habits.

Frequent changing of formulas because the "milk does not agree with the baby" should be avoided. Gastrointestinal allergy occurs in infants and is frequently relieved by a change to a hypoallergenic milk. Usually a feeding problem is due to underfeeding, technical errors or a physical disturbance in the infant. A formula of average composition will agree with most infants.

*A knowledge of the personality pattern of the parents is most helpful in anticipating and preventing many types of feeding difficulties in the infant.*

**Underfeeding.** Underfeeding is evidenced by restlessness and crying, and by failure to gain weight adequately in spite of complete emptying of the breast or bottle. Underfeeding may also result from the infant's failure to take a sufficient quantity of food even though it is offered. In such instances the frequency of feedings, the mechanics of nursing, the size of the holes in the nipple, the adequacy of eructation of air, as well as the possibility of systemic disease in the baby, should be investigated. The extent and duration of underfeeding determine the clinical manifestations. Constipation, failure to sleep an adequate amount of time, irritability and excessive crying are to be expected. There may simply be an inadequate gain, a failure to gain or an actual loss in weight. In the last instance the skin becomes dry and wrinkled, subcutaneous tissue disappears, and the infant assumes an "old man" appearance. Deficiencies of vitamins A, B, C and D and of iron and protein may be responsible for characteristic clinical manifestations.

*Treatment* consists in increasing the fluid and caloric intake, correcting deficiencies in vitamin and mineral intake, and instructing the mother in the art of infant feeding.

**Overfeeding.** Overfeeding may be quantitative or qualitative. As a rule, infants can be depended upon not to take excessive quantities; but occasionally an infant has postprandial discomfort from eating too much, and he may gain weight excessively. Diets too high in fat delay gastric emptying, cause distention and abdominal discomfort and may cause excessive gain in weight. Diets too high

in carbohydrate are likely to cause undue fermentation in the intestine, resulting in distention and flatulence, and in too rapid gain in weight. Such diets may be deficient in essential protein, vitamins and minerals. Formulas too high in caloric content in the first week or two of life are likely to result in loose or diarrheal stools. Regurgitation and vomiting are frequent symptoms of overfeeding.

**Regurgitation and Vomiting.** The return of small amounts of swallowed food during or shortly after eating is termed "regurgitation" or "spitting up." More complete emptying of the stomach, especially when it occurs some time after feeding, is termed "vomiting." Within limits, regurgitation is a natural occurrence, especially during the first half year or so of life. Regurgitation can be reduced to a negligible extent, however, by adequate eructation of swallowed air during and after eating, by gentle handling, by avoidance of emotional conflicts, and by placing the infant on his right side or abdomen for a nap immediately after eating. One should also ensure that the head is not lower than the rest of the body during the rest period.

Vomiting is one of the most common symptoms in infancy and may be associated with a wide variety of disturbances, both trivial and serious. Its cause should always be investigated (see p. 647).

**Loose or Diarrheal Stools.** Acute infectious diarrhea and chronic diarrheal conditions are discussed elsewhere; here there is consideration only of mild disturbances of a dietary origin.

The stool of the breast-fed infant is naturally softer than that of the infant fed cow's milk. From about the fourth to the sixth day of life the stools go through a transitional stage and are rather loose and greenish-yellow, and contain mucus; but within a few days the typical "milk stool" appears. Subsequently the use of laxatives or the ingestion of certain foods by the mother may temporarily be responsible for an infant's loose stools. Excessive intake of breast milk may also increase the frequency and decrease the consistency of the stool. Actual diarrhea in a breast-fed infant is unusual and should be considered infectious until proved otherwise.

Though the stools of artificially fed infants tend to be firmer than those of breast-fed infants, under certain circumstances loose stools may result from artificial feeding. In the first two weeks or so of life, overfeeding is likely to cause loose, frequent stools. Late

formulas which are too concentrated or whose sugar content is too high, especially in lactose, may be responsible for loose, frequent stools. Many of the temporary diarrheal disturbances in artificially fed infants, however, are the result of contaminations of food such as would not disturb an older child, and not serious enough to cause prolonged disturbance in the infant. The ease with which artificially fed infants acquire diarrheal disturbances and the potential seriousness of them are strong arguments for extreme care in providing a food supply free of pathogenic bacteria.

Mild diarrheal disturbances due to overfeeding respond quickly to temporary decrease or cessation of feeding. The temporary omission of all solid food and of one or several milk feedings, with the substitution of boiled water or 5 per cent glucose solution in water or in a balanced electrolyte solution, is usually all that is required.

**Constipation** (see also p. 652). Constipation is practically unknown in breast-fed infants who receive an adequate amount of milk, and is rare in artificially fed infants receiving an adequate diet. The status of the stool, and not its frequency, is the criterion of constipation. Although most infants have one or more stools daily, an occasional infant will have a stool of normal consistency only at intervals of thirty-six to forty-eight hours. Whenever constipation or obstipation is present from birth or shortly thereafter, a rectal examination should be performed. Tight or spastic anal sphincters occasionally may be responsible for obstipation, and correction usually follows prolonged finger dilatation performed twice or three times a day. Anal fissures or cracks may also cause constipation. If irritation is removed, healing usually occurs quickly. Aganglionic megacolon may be manifest by constipation in early infancy.

Constipation in the artificially fed infant may be due simply to an insufficient amount of food or fluid and is corrected by increasing the intake. In other instances it may result from diets too high in fat or protein or deficient in bulk. Simply increasing the amount of sugar in the formula may be corrective in the first few months of life. After this age better results are obtained by adding or increasing the amounts of cereal, vegetables and fruits. Prune juice ( $\frac{1}{2}$  to 1 ounce) may be given as a temporary measure, but it is better to add foods with some bulk. Enemas and suppositories should never be more than temporary measures. Milk of magnesia may be

given in doses of 1 or 2 teaspoonfuls, but should be reserved for emergencies.

**Colic.** The term "colic" is used to describe a frequent symptom complex of paroxysmal abdominal pain, presumably of intestinal origin, and of severe crying. It usually occurs in infants under three months of age.

The clinical pattern is characteristic. The attack usually begins suddenly; the cry is loud and more or less continuous; so-called paroxysms may persist for several hours; the face is congested and may be somewhat cyanotic, or there may be circumoral pallor; the abdomen is distended and tense; the legs are drawn up on the abdomen, although they may be momentarily extended; the feet are often cold; the hands are clenched. The attack may terminate only when the infant is completely exhausted, but often there is relief with the passage of feces or flatus.

Certain infants seem to be peculiarly susceptible to recurrent attacks of colic. The cause of the recurrent attacks is usually not apparent, although it may be associated with hunger and with swallowed air which has passed into the intestine. Overfeeding may also cause discomfort and distention, but rarely to the degree seen in colic. Certain foods, especially those of high carbohydrate content, may be responsible for excessive fermentation in the intestines, but only rarely does a change in diet prevent further attacks of colic. Crying from intestinal discomfort is seen in infants with intestinal allergy, but colic is not limited to this group. Intestinal obstruction or peritoneal infection may mimic an attack of colic. Recurrent attacks are frequently seen late in the afternoon or evening, and this suggests the possibility of some preceding event in the household routine as a possible cause. Worry, fear, anger or excitement may cause vomiting in an older child, and such emotional disturbances may result in colic in an infant. Certainly no single etiologic factor consistently accounts for colic, nor does any method of treatment consistently provide satisfactory relief.

Holding the baby upright or permitting him to lie prone across the lap or on a hot water bottle or heating pad is occasionally helpful. Passage of flatus or fecal material spontaneously or with expulsion of a suppository or enema sometimes affords relief. Carminatives before feedings are ineffective in preventing the attacks. Sedation is occasionally indicated for a prolonged attack, and sometimes over a period of time for parent and/or

child if other measures fail. The prevention of attacks should include adequate feeding techniques, including burping, the provision of a stable emotional environment, the search for a possible allergenic food in the infant's or nursing mother's diet, and avoidance of underfeeding. The condition rarely persists after three months of age.

## FEEDING DURING THE SECOND YEAR OF LIFE

Most infants naturally adapt themselves to a schedule of three meals a day by about the end of the first year of life. Though considerable latitude in the diet of the individual infant must be permitted to allow for personal idiosyncrasies and family habits, the mother should be given an outline of the daily basic dietary needs. These are as follows:

Milk.....	$\frac{3}{4}$ to 1 quart
Meat (fresh, lean) or fish.....	1 serving (5 to 6 per week)
Liver.....	1 serving or more per week
Eggs.....	1 daily (5 to 6 per week)
Vegetables (1 raw, 1 pigmented).....	2 or more servings
Fruits (1 fresh).....	2 or more servings (one of which should be citrus or tomato juice)
Butter or oleomargarine.....	2 teaspoonfuls or more
Bread and cereals (whole grain).....	Sufficient to meet caloric needs
Vitamin D.....	800 to 1000 I.U.
Salt (iodized).....	For seasoning

**Reduced Caloric Intake.** Toward the end of the first year of life and during the second year, owing to the constantly decelerating rate of growth, there is a gradual reduction in the infant's caloric intake per unit of body weight. In addition, it is not unusual for him to have temporary periods of disinterest in food in general or in certain articles of it. Failure to recognize these features, especially the decreasing caloric needs, results in attempts to force feeding. The natural reaction of the child is rebellion, and feeding problems ensue. Prevention is much more effective than are methods of correction, and the changing pattern of the infant's food habits during the second year of life should be explained to the mother before it makes its appearance.

**Self-Selection of Diet.** Clara Davis demonstrated that infants in institutions, when given the opportunity, will select a balanced diet. Though at intervals the daily intake may be at variance with the usual pattern, and certain foods will be eaten in excessive amounts and others refused, over the longer range the pattern of eating is average and

adequate. In principle, such a policy may be adopted in the home so far as the child is permitted a rather wide latitude in his choice of foods. Though it is not possible to have a wide variety of foods of the same class, such as a variety of meats, at each meal, strong likes or dislikes of children for particular foods should be respected. Spinach is an example of an unessential food which has been unduly emphasized and has been responsible for many feeding difficulties. When the rejected foods include essential items such as milk and eggs, then the child must be slowly "educated" to eat them, provided he is not allergic to them.

Under average circumstances the child should also determine the quantity to be eaten of a given food as well as of the entire meal. Such a plan can and does work under favorable circumstances. At this age the child should be fed separately from the rest of the family. When he eats with them, their eating habits will influence the development of his. Eating habits developed during the first two years of life are usually protracted for years.

**Self-Feeding by Infants.** Before the infant is a year of age he is able and should be permitted to participate in the act of feeding himself. By six months or so he can hold his bottle. Within another two or three months he can hold a cup. The introduction of zwieback, graham crackers and bacon by the time he is seven to eight months of age gives the infant something which he can hold and thus learn one of the principles of self-feeding. He may use a spoon for feeding himself as soon as he can hold it and direct it to his mouth. This may be by ten to twelve months of age. Mothers often inhibit this learning process because of their objection to the messiness incident to the learning of adequate control.

Acquisition of the ability to feed himself is an important step in the infant's development of self-reliance and of a sense of responsibility and has favorable repercussion in the years which follow. By the end of the second year of life the infant should be largely responsible for his feeding.

## FEEDING OF OLDER CHILDREN

In comparison with the supervision commonly maintained over the feeding of infants, the diets of children beyond the age of two years are badly neglected. Though it is desirable that children should not be aware of constant supervision of their dietary habits and that they should be given every opportunity to

form eating habits naturally, the diets of all children should be supervised. Surveys of dietary habits of children in various economic groups reveal a high incidence of inadequate diets and of malnutrition. Although the nutritional requirements per unit of body weight are constantly decreasing with increasing age (110 calories per kilogram in infancy; 50 calories per kilogram at fifteen years), at all times the need for calories as well as for protein, vitamins and minerals is relatively greater than it is in the adult.

**Daily Basic Diet.** Parents should be given a daily basic diet for the child from which the family menu can be prepared. It is essential that the entire family partake of the same diet and that the sense of "being on a diet" be avoided. The quantity of the intake after the basic requirements have been met can in most instances be determined by the healthy growing child; the obese child is an exception. A history of the dietary habits of the child is essential for evaluation of his nutritive intake, but such histories are often unreliable. More dependable information can be secured by providing the mother with a number of dietary history blanks such as the one illustrated in Table 26, on which she can record the daily intake for several representative days. From such information, corrections in the diet may be made more effectively. This table also contains the recommended daily dietary intake.

*Adequate quantities of all the essential classes of foods must be provided in order to avoid specific nutritional deficiencies.* There is no harm in the child's knowing the content of a basic diet and the reason for it. Actually, there is benefit, if it is presented and received in a natural way.

The following is a daily menu which will provide all the essential nutrients:

Breakfast:	Citrus fruit or tomato juice Cereal—whole grain or enriched Egg Whole-wheat toast Butter Milk
Lunch:	Sandwich with whole-wheat bread or Casserole dish—containing meat or meat substitute and starchy vegetable Green vegetable, raw Milk Custard, pudding, cake, ice cream or gelatin dessert
Dinner:	Meat—fish—liver Potatoes, rice or spaghetti Green vegetable

Whole-wheat bread, butter  
Milk  
Fruit  
Vitamin D (throughout childhood)

**Eating Habits.** As stated previously, eating habits formed in the first year or two of life have a distinct effect upon those of subsequent years. Feeding difficulties between the ages of two and five years frequently result from too great parental insistence on eating and too great anxiety when the child does not conform to some arbitrary standard. Negativistic reactions by the child are natural consequences, and correction requires improvement in the parent-child relationship. Other factors which disturb eating are too much confusion at mealtime, insufficient time for eating, either on the part of the adult or of the child, food dislikes of other members of the family, and poorly prepared and unattractively served food. A comfortable chair of proper height with a foot-rest is important for a child's ease at the table.

It is good practice to call the child from play fifteen or twenty minutes before meal-times. This allows time for going to the toilet and washing the hands and face and cooling off from strenuous activity before eating. At this time it is wise to arrange for some diversion such as reading or helping with final preparations for the meal. This is an excellent time especially for younger children to spend with the father, reading or playing quiet games. Mealtimes should be happy. Discussion concerning the food, except for occasional favorable comments, should be avoided, and the conversation should be on subjects of interest to the entire family. The child should feel that he is part of the family group. The child's appetite should be respected; if his desire for food at times is below average, there should be no persuasion to eat more. Adults should realize that eating habits are taught better by example than by formal explanation.

**Lunches between Meals.** During the second year and even for several years thereafter, orange juice or other fruit juice or fruit together with a cracker may be given in either or both of the midmeal periods. For older children midmeal nourishment should be avoided if it reduces the appetite for the following meal. When a snack after school results in greater enthusiasm and energy for play and does not reduce the appetite for the evening meal, it should be encouraged. Fruits are especially recommended for such lunches.

There are differences of opinion concerning midsession lunches in school. Though in

Table 26. Record of Dietary History\*

TYPE OF FOOD	DAILY CONSUMPTION	RECOMMENDED ALLOWANCE FOR GROWING CHILD
I. Milk.....	Total.....	1½ pt.-1 qt.
	With meals..... Between.....	
	With cereal..... In cooking.....	
Milk products.....	Cheese..... Cream.....

HYGIENE

Parents are besieged with and sometimes overwhelmed by a barrage of advice on the bringing up of children. Articles in maga-  
zines, syndicated columns in the daily press, advertising, radio, television and in fact all available forms of communication are being utilized to bring information to this receptive group. Much of the advice is good, but much of it is misinterpreted and confusing. The role of the physician as a health educator is, as a result, that of an interpreter as well as a purveyor.

**Habits.** The infant begins the development of habits at birth. These habits are usually considered good or bad as they reflect the ability to conform comfortably to what is expected. The demands made by the family are frequently out of line with the ability or readiness of the child to learn, and conflicts arise which a physician may help to explain and to resolve. Children acquire habits by repetition of an act, and parents should be reminded that it is much easier to form a habit than to change one. Praise, encourage-

ment and attention, even though of a negative sort, fortify a habit, whereas lack of attention serves to discourage repetition of an act. What parents do rather than what they say is important.

Consistency of action by the parents is essential if a child is to be helped rather than confused. Children seem to do equally well with a strict or a laissez-faire discipline if they are sure of what is expected of them. If parents can appreciate that their responsibility in guiding habit formation is to help the child gain increasing independence at his own optimal rate, much concern over trivia will be avoided. Children want to conform to what is expected of them, and effort as well as actual achievement should be praised. Comparison with others, the setting of too rigid goals, and impatience with lack of early success result in frustration and tensions.

Habit formation is usually thought of in relation to establishment of eating, sleeping, bowel and bladder patterns. Regularity and relatively automatic functioning in these fields are necessary before children are free to progress to more complicated learning.

**Eating.** Eating habits of infants are discussed on page 112, of older children on page 133.

**Sleep.** There is considerable variation in the amount of sleep required by different children. Many children, however, get too little rest, and often the symptoms of irritability, lethargy, anorexia, temper tantrums and perhaps increased susceptibility to infection result. Many behavior problems are precipitated by fatigue.

Most infants sleep sixteen to twenty hours a day during the first half year; by six months of age they will sleep through the night and are awake for periods totaling six to eight hours. By one year of age the child sleeps an hour or two less and by two years of age averages twelve to fourteen hours a day. The need for sleep gradually decreases, but rarely becomes less than ten hours during the pediatric age range. A nap during the day is desirable until school interferes with this routine, and rest periods should have an important place in kindergarten and first and second grade schedules.

Early establishment of regularity of bedtime is most important; nowhere in the field of habit formation is consistency more important. The presleep period should be free of excitement, rushing, scolding and physical activity. Stimulation of children by exciting stories, radio, television, active play or by a

battle of wills should be avoided. A family story, quiet discussion of happy events of the day, a warm bath and reassurance of love and affection are conducive to easy sleep. Children, even when sleepy, normally do not want to stop doing something interesting. The habit of going to bed on schedule and to sleep promptly can be established and maintained by a consistent and understanding approach.

Infants and children should have their own beds and, if possible, their own rooms. The sleeping room should be ventilated, but free of drafts. Bed clothing is frequently too heavy and should be varied with the temperature. Overall sleeping garments for infants who may get uncovered in cold weather are useful. Position during sleep is relatively unimportant. The position of infants, especially of premature ones, should be changed often enough to prevent moulding of the cranium from chronic pressure on one area.

**Disturbances of sleep** (see p. 89).

**Elimination.** Control of the anal and bladder sphincters is naturally acquired by most infants during the second or third year of life. Efforts to "train" a baby before he is ready for voluntary control of his sphincters are usually disastrous and frequently lead to an unhappy parent-child relationship. He is not ready to use the toilet until he is old enough to understand what it is for and to let his mother know of his needs, until his bowel movements come at fairly regular times, and until he is willing to sit on the toilet. A comfortable seat with a rest for the feet and a strap for safety should be provided. Suppositories or soap sticks have no place in the establishment of regular bowel habits, and coercive methods of any sort are contraindicated.

By about eighteen months of age most toddlers have acquired enough bladder control to retain urine for two hours or so. At this age they may be encouraged to sit on the toilet and void. It is best to make initial efforts just after meals or naps and when the child is dry and likely to void readily. Other routines or interesting play should not be interrupted for this purpose. Nocturnal control of urination is not usually developed until the third year of life or later.

**Exercise.** The normal infant or child, in a reasonable environment, will have sufficient muscular activity for good growth and development. The young infant begins to develop his large muscles by kicking, stretching, crying and squirming. He should be allowed to do so several times a day on a safe flat surface unencumbered by clothes. He should be

provided with easily grasped toys to develop hand use. Limits for safety's sake must be provided when he crawls and begins to walk, but his activities at this stage should not be limited to a "play pen." This piece of furniture was designed for adult convenience, not to aid the child's development. Toddlers should be provided with safe areas both indoors and outdoors in which to run, climb and explore. They need large blocks, push and pull toys, materials for imitative play, and the privilege of getting dirty and playing with water. Children's toys should, in general, be washable, not easily broken, free of sharp edges and splinters and of removable parts that can be swallowed or aspirated.

Schools should provide an opportunity for universal participation in organized sports. Intramural teams can offer the less well coordinated boy or girl an opportunity to take part in group sports.

**Sunlight and Fresh Air.** Sunshine and fresh air are essential for the development and maintenance of sound health. Dependence is no longer placed on sunlight for the prevention of rickets, but many other benefits accrue from it. It is unnecessary, however, to make a fetish of exposure of young infants to the sun, particularly in cold weather. Care should always be taken to avoid sunburn. Outdoor play should be encouraged at all ages when the weather permits and clothing is adequate. Fresh air should be provided indoors by adequate ventilation.

**Clothing.** There have been tremendous improvements in the functional design and in the materials of infant's and children's clothing. The diaper is still standard equipment, but tapes, drawstrings, many tiny buttons, frilly dresses and bulky winter clothes have largely been replaced by elastic materials, grippers, zippers, a few large buttons, slip-on shirts and pants and by new materials of lighter weight for cold weather. The principles guiding the choice of good clothing for children are attractiveness and color, simplicity in design, ease of use, softness of texture, lightness of weight, washability, relative looseness of fit and freedom from irritation to the skin. Knitted cotton is usually best next to the body. Children should be dressed appropriately for the environment. There is a universal tendency to overdress children in the winter which frequently results in excessive perspiration. Extra water-repellent garments are easily put on a child to secure the warmth and protection needed for outdoor

activities, and they should be removed as soon as he re-enters the warm house or schoolroom. The legs of both boys and girls should be covered in cold weather.

Layettees are usually too elaborate. Infants need shirts with and without sleeves, nightgowns, diapers, socks or booties, a sweater and an outer garment with a hood for outdoor winter use. Rubber or plastic pants should be loose enough to permit evaporation and should not be used except for relatively short periods to avoid otherwise troublesome situations. Lightweight cotton blankets are generally preferable to heavy woolen ones; a well made sleeping bag is satisfactory for cold weather.

Children's shoes are discussed on page 1253.

**Cleanliness.** Certain aspects of cleanliness such as the bath, washing at mealtimes and at toilet time, the use of a handkerchief and of a napkin, brushing the teeth and some responsibility in caring for clothing are essentials that should be reduced to the level of habitual reactions as early in life as possible. Formation of habits of personal cleanliness is encouraged, like all other habits, by the examples of parents, by praise and recognition of effort, by pleasant rather than unpleasant experiences, by consistency and by gradually decreasing assistance on the parents' part. Many parents need help in achieving a perspective on healthy cleanliness which lies somewhere between asepsis and filth.

A daily bath for infants is a good rule. In warm weather more frequent sponging may be necessary. As soon as the umbilicus has healed, the infant may be immersed in a basin or tub. The room should be comfortably warm; supplies should be ready at hand; a safe flat working surface must be available; care must be taken not to let the infant slip or fall; and the experience should be made a happy, playful one. A regular time for bathing as well as for other routine activities should be established. A nonirritating soap is lathered over the trunk and extremities with care to avoid the eyes and mouth, and the baby is then rinsed with fresh, comfortably warm water. The scalp should be washed as needed. The skin is patted dry, with special attention to the creases.

Oil, powder or lotion is usually not necessary, although their use is sometimes helpful for dry skins and in the diaper area. Caution should be used to avoid inhalation of any powder, and zinc stearate should not be permitted in the nursery (see p. 799).

The face is washed with clear water, except when soap or oil is necessary to remove dried excretions or vomitus.

The external ear may be washed with a soft cloth; dried accretions in the creases may be removed with a cotton-tipped applicator moistened with oil. The ear canal, except at its opening, should not be cleaned by an untrained person.

The eyes usually require no special care. Accumulated secretions in the corner of the eye should be wiped out with a piece of cotton saturated with clear water.

The nose does not need any cleaning unless there are dried secretions at the openings of the external nares. They may be removed with a dry or moistened cotton-tipped applicator. Oil should not be used.

Under no circumstances should attempts be made to clean the mouth, since the mucous membrane is easily damaged and is then especially susceptible to infection.

Brushing of the teeth is not advised until the third year of life. Before this time they may be cleaned occasionally with a cotton-tipped applicator saturated with saline or sodium bicarbonate solution.

Nails need trimming when they protrude beyond the ends of the fingers or toes. Toe

nails should be cut straight across without rounding the corners so that "ingrowing toenails" may be prevented.

The bathing of older children requires no special consideration. In summertime there should be daily baths; in the winter months this is not necessary and, in children with dry skins, should be avoided. In the latter instance, two to four baths a week are adequate depending on the state of cleanliness. Baths should be taken preferably at night to lessen the degree of chafing, which is also reduced if the skin is dried thoroughly. Anointing the skin with oil or skin lotion helps to avoid chafing of dry and sensitive skins.

The genitals should be washed at bath time. In the uncircumcised male infant the foreskin may be retracted as far as possible without trauma. Adhesions will usually be broken as the child grows older, and no strenuous effort need be made to break them. Smegma may be removed from the vulva with a soft cloth or a cotton pledget saturated with oil. Genitals of both sexes should be rinsed with clean water at the end of the bath to prevent irritation from soap, which otherwise might dry on the mucous membranes.

JOHN B. BARTRAM

## PREVENTIVE PEDIATRICS

Prevention of disease, including psychologic as well as organic disorders, ranks with treatment as a goal of pediatric practice, since harmful physical and mental experiences during infancy and childhood may leave permanent handicaps.

In a narrow sense the term "preventive pediatrics" signifies only the avoidance of illness or disability. The broader aspect, however, encompasses more than simply averting illness and accidents; it also includes measures to lessen the progress of chronic disease. Early diagnosis when health can still be restored or preserved is essential and obviously requires widespread application of the health examination during infancy and the preschool, school and adolescent periods.

Measures aimed at preventing the onset of physical or psychogenic illness or disability may be called *primary preventive* procedures, while steps to promote and preserve health by controlling disabilities may be termed *secondary preventive* measures.

### PRIMARY PREVENTION OF DISEASE

#### PERINATAL FACTORS IN NEONATAL DISTURBANCES

Prevention of disease and handicaps among children can begin long before birth. Even during their childhood girls are preparing to bear healthy children by achieving optimal health; immunization against poliomyelitis and having rubella in the premarital years are examples of specific preventive measures.

In the *prenatal* period general practitioners and obstetricians can do much to assure that the infant will be born healthy. Diagnosis and treatment of *maternal infections* such as syphilis and gonorrhea and prevention of other infections in the pregnant woman (human immune serum globulin after exposure to infectious hepatitis at any time in pregnancy and after exposure to rubella in the first trimester) will eliminate some hazards of the neonatal period. Minimal use of radiation

during pregnancy is advisable because of adverse effects on the fetus; if it is used, a record of the amount should be kept in order to prevent uncontrolled exposure of the infant should radiation be required postnatally.

The offspring of healthy women whose *nutrition* has been adequate throughout pregnancy have fewer difficulties during the neonatal period than do infants of mothers whose nutritional status is less good.

Mortality from erythroblastosis fetalis (hemolytic disease of the newborn) can be markedly influenced by determining the blood type of the pregnant woman and her husband prenatally and by obtaining periodic antibody titers to detect iso-immunization when that likelihood exists. Prompt treatment of hemolytic disease depends on prenatal diagnosis of the possibility that iso-immunization may occur. Mortality among infants of diabetic mothers can also be reduced by appropriate management of the maternal disease in the prenatal period and subsequently of the delivery and of the infant.

The most important problem of infancy is premature birth. From 60 to 70 per cent of deaths during the first year of life occur during the first month; of these fatalities, about 60 per cent occur among the 10 per cent of infants who weigh less than 5 pounds 8 ounces at birth. In addition to increased mortality, serious neurologic sequels occur with greater frequency. The majority of factors responsible for premature births can be influenced by prenatal medical care. Advice during pregnancy can often avoid premature labor among women who have a previous history of premature delivery, those with multiple pregnancies, and those who are chronically below par in various respects. Adequate prenatal care can do much to reduce the incidence of toxemias of pregnancy, which contribute significantly to premature birth because of the frequent necessity for interruption of pregnancy before term. The prevention of prematurity offers more hope for preserving life and preventing postnatal handicaps than do measures which can be taken after delivery.

The *natal period* from onset of labor to delivery of the infant is one of great risk, and a number of preventable anesthetic, analgesic and obstetric circumstances contribute to morbidity in the neonatal period and to mortality.

In the *neonatal period* (birth to one month of age) there are many opportunities for preventive measures, which include prompt physical examination of the newborn infant to

detect remediable congenital anomalies and acquired illness, measures to protect the infant from infection and avoidance of the overuse of drugs (for example, unnecessary use of oxygen and vitamin K).

#### PREVENTION OF INFECTION

**Routine Immunizations.** The prevention of infectious diseases by immunization is the most familiar aspect of preventive pediatrics. Today it is routine practice to immunize infants against *diphtheria*, *pertussis*, *tetanus*, *smallpox* and *poliomyelitis* during the first year of life.

**Active immunization against diphtheria, pertussis and tetanus** can be accomplished simultaneously by combined alum-precipitated or aluminum hydroxide-adsorbed diphtheria and tetanus toxoids and pertussis vaccine ("triple toxoid"). It is desirable that the mixture of antigens be such that 0.5 ml. contains adequate amounts of diphtheria and tetanus toxoids for one dose and 4 N.I.H. units of pertussis vaccine. The minimum is three intramuscular injections of combined toxoid-vaccine mixtures given at intervals of four weeks. This interval has the advantage of producing immunity rapidly, but the interval may be extended to three to six months. (See also chapters on Diphtheria, Tetanus and Pertussis.) Immunization of infants is usually started at one or two months of age, although satisfactory results have been reported from immunization begun at birth.

Toxoid and vaccine may be given intramuscularly in the gluteal, the lateral thigh, the deltoid or the triceps muscles. The injections are usually given in the lower extremities during infancy and in the arms of older children. Only one injection of a series should be given into the same muscle mass.

Occasionally there are reactions causing fever, excessive crying and localized swelling, redness and tenderness at the site of injection. In such instances the next dose of combined toxoid-vaccine should be drastically reduced, or the immunization should be completed by using diphtheria and tetanus toxoids and pertussis vaccine separately. When a convulsion occurs as part of the reaction, further immunizing procedures should be postponed for at least a year. Further administration of pertussis vaccine may be hazardous.

Children not immunized during infancy may be given basic immunizations by three injections of "triple toxoid" up to the age of six years; three injections of diphtheria-tetanus toxoid (precipitated or adsorbed) are

advised for those between the ages of six and ten years. Patients ten years of age and older should be tested initially for sensitivity to diphtheria toxoid unless "adult" type of toxoid is used (see footnote of Table 27). The toxoid sensitivity test (modification of the Moloney and Zoeller tests) consists in an intradermal injection of 0.1 ml. of a 1:100 dilution of fluid diphtheria toxoid. The test is read at forty-eight hours; a positive reaction consists of an area of erythema and induration 1 cm. or more in diameter. If the Schick test is positive and the sensitivity test is negative, the individual may be immunized with standard 0.5-ml. doses of diphtheria-tetanus combined toxoids at intervals of four to six weeks. If the Schick and sensitivity tests are both positive, it is not safe to administer diphtheria toxoid, except as the sensitivity test is only moderately positive, when immunization should be carried out cautiously by injecting 0.05 ml. of fluid diphtheria toxoid subcutaneously. If no further untoward reactions occur, this dose may then be doubled at weekly intervals until four injections (0.75 ml.) have been given.

Primary immunization of older children may apparently be safely performed with the "adult" type of diphtheria-tetanus toxoid, which contains less antigen than standard toxoid.

Tetanus toxoid (precipitated or adsorbed) rarely causes local or systemic reactions, so that primary immunization of children over the age of ten may be accomplished by two injections of 0.5 ml. each at an interval of at least one month and not longer than four months. When fluid tetanus toxoid is used, three injections of 0.5 ml. are administered.

Children over the age of six years are usually not immunized against pertussis. If immunization is considered advisable, as when there are small infants in the family for whom pertussis would be dangerous, three intramuscular injections of alum-precipitated or aluminum hydroxide-adsorbed *H. pertussis* vaccine at intervals of at least one month and containing a total dose of at least 12 N.I.H. units should be given. If the saline-suspended vaccine is used for rapid protection, three injections should be made at intervals of one to four weeks, with a total dose of 12 N.I.H. units.

"Booster" or stimulating injections of toxoid and vaccine are given at regular intervals after the initial series of immunizing inoculations to assure maximum immunity. The first "booster" injection should be given one year

after completion of the primary immunization and subsequent "boosters" at intervals of three years. The recall of antibodies is accomplished by extremely small amounts of antigen, so that "booster" doses after the first one may consist of only one fifth to one half of the individual doses of the primary immunization.

The Schick test is seldom used among children under ten years of age who were immunized in infancy. The periodic administration of booster doses of diphtheria toxoid is safer and more effective than relying on the Schick test as a guide for additional immunization. After the age of ten years the need for booster injections should be determined by a Schick test, one at twelve years of age and another at sixteen to eighteen years. Schick tests and diphtheria toxoid sensitivity tests may be avoided among older children by using the "adult" type of diphtheria toxoid containing only 2 Lf. in 0.5 ml.

In general, alum-precipitated or aluminum hydroxide-adsorbed toxoid-vaccine (diphtheria, tetanus and pertussis) is used for recall or booster immunization unless a prompt rise in immunity is required because of exposure to one of the diseases. In such instances fluid toxoids and saline-suspended pertussis vaccine are advised because the more prompt absorption of these substances accelerates antibody formation (see Table 27).

Contraindications to routine immunization of infants and children with toxoid-vaccine are acute illness, obvious cerebral damage or a history of convulsive disorder. In the event of acute illness, immunization should be postponed temporarily. In the other situations immunization should be delayed until after infancy, when it may be started cautiously with small doses of the antigens administered separately, and with the child under close observation. (See above for recommendations when there has been an untoward reaction to a previous immunization.)

A relationship between the localization of paralysis in poliomyelitis and the site of recent toxoid or vaccine injections has been observed. Where poliomyelitis is epidemic, routine intramuscular or subcutaneous injections of toxoids and vaccines should be limited to children under the age of six months. When a child older than six months has been exposed to a disease for which passive or active immunization is advisable, the immunization is justified during a poliomyelitis epidemic. Administration of poliomyelitis vaccine during an epidemic is considered safe, but it offers no immediate protection.

**Vaccination against smallpox** (see p. 501) should be performed during the first year of life, usually after immunization against diphtheria, tetanus, pertussis and poliomyelitis. Revaccination every five years is advisable. When there is any possibility that exposure to smallpox has occurred and there has been an interval of more than one month since the last successful vaccination, revaccination is recommended. Vaccination against smallpox is contraindicated for children with eczema or dermatitis and for household contacts of children with these conditions, to avoid secondary vaccination or generalized vaccinia.

**Vaccination against poliomyelitis** should be performed in infancy at the time of the initial diphtheria-pertussis-tetanus immuniza-

tions (see Table 27) or a month or so after their completion by two injections of poliovirus vaccine one month apart; seven months after the second inoculation a third injection of vaccine should be given. This schedule of administration of poliovirus vaccine is thought to confer effective immunity in most persons for an indefinite number of years. Some observers, however, believe that the probability of significantly greater protection afforded by a fourth injection one year after the third one justifies it as a regular procedure.

**Special Immunizations.** Active immunizations against rabies, mumps, Rocky Mountain spotted fever, virus influenza, typhoid fever and tuberculosis are indicated under certain circumstances. Immunizations against these

Table 27. Recommended Immunization Procedures

<b>I. Primary Immunization</b>	
1-2 Months of age:	0.5 ml. of diphtheria-pertussis-tetanus antigen mixture (D.P.T.*) intramuscularly in the left gluteus maximus
2-3 Months of age:	0.5 ml. of D.P.T.* in the right gluteus maximus; 1.0 ml. of poliomyelitis vaccine at a different site, unless a commercial vaccine containing the 4 antigens should become available
3-4 Months of age:	0.5 ml. of D.P.T.* in the left vastus lateralis or right deltoid; 1.0 ml. of poliomyelitis vaccine as described above
5 Months of age:	Smallpox vaccination over the left deltoid or triceps
6 and 7 Months of age:	Poliomyelitis vaccine, if not given earlier with D.P.T.,* 2 doses of 1.0 ml., respectively; in the deltoid or triceps muscle
<b>II. Routine Recall (Booster Injections)</b> (Give in the deltoid or triceps muscle)	
11-14 Months of age:	Poliomyelitis vaccine, 1.0 ml. (give 7 months after 2 primary injections)
18 Months of age:	0.5 ml. of D.P.T.* (first "booster")
3-4 Years of age, or 2 years after first "booster":	0.5 ml. of D.P.T.*
6-7 Years of age:	0.1 ml. of diphtheria-tetanus toxoid
9-10 Years of age:	0.1 ml. of diphtheria-tetanus toxoid
Every 3 years thereafter:	0.5 ml. of "adult" type of diphtheria-tetanus toxoid† or, if Schick test is known to be negative, 0.1 ml. of tetanus toxoid
<b>III. Exposure Recall (Booster) Injections</b>	
A. Upon intimate exposure to whooping cough or during an epidemic, assuming that the child has not had a routine recall injection in the past 2 months, give saline-suspended <i>H. pertussis</i> vaccine subcutaneously in a dose of 4 N.I.H. units	
B. Exposure to diphtheria: Children under the age of 5 years, 0.5 ml. of diphtheria toxoid; children 5 to 12 years of age, 0.1 ml. of toxoid; those over the age of 12, 0.01 ml. of standard diphtheria toxoid or 0.5 ml. of "adult" type of toxoid.	
C. Exposure to tetanus	
1. For mild to moderately severe scratches, burns, puncture wounds or dog bites, 0.5 ml. of fluid tetanus toxoid subcutaneously, provided not more than 8 years have elapsed since last toxoid injection. When interim is 9 years or more, follow procedure in 2 below.	
2. For extensive contaminated wounds combined active-passive immunization by giving 0.5 ml. of fluid tetanus toxoid intramuscularly and 5000 units of tetanus antitoxin intramuscularly is advisable	
<b>IV. Revaccination against Smallpox</b>	
Every 5 years and during an epidemic ("No reaction" means that the vaccine is not potent, and not that the patient is immune)	

Adapted from Report of the Committee on The Control of Infectious Diseases, American Academy of Pediatrics, Evanston, Illinois, 1957.

\* D.P.T.—alum-precipitated or aluminum hydroxide-adsorbed diphtheria and tetanus toxoid containing at least

4 N.I.H. units of *H. pertussis* organisms.

† 2 Lf of diphtheria toxoid and 5-15 Lf. of tetanus toxoid per 0.5 ml.

Table 28. Special Immunizations for Foreign Travel

<i>Vaccine</i>	<i>Individual Dose*</i>				<i>No. Doses</i>	<i>Interval</i>	<i>Mode of Administration</i>	<i>Booster</i>

1st dose . . . . .	0.2 ml.		0.3 ml.		3-4	1-4 weeks	Subcutaneously	0.1 ml. intradermally every 1-2 years
2nd dose . . . . .	0.2 ml.		0.6 ml.					
3rd dose . . . . .	0.3 ml.		0.6 ml.					
4th dose . . . . .	0.3 ml.		None					

\* All doses are based on subcutaneous administration.

diseases are discussed in the appropriate chapters of this volume.

Increased travel to foreign countries has made it necessary for many infants and children to receive special immunizations not necessary in North America. Information about the required and recommended immunizations in various parts of the world can be obtained from health departments or from publications of The Public Health Service, Washington, D.C. (see also Table 28).

*Passive immunizations* against measles, rubella, infectious hepatitis and poliomyelitis are often carried out by injection of gamma globulin when susceptible persons are known to have been exposed. Passive immunization against diphtheria, pertussis, mumps, tetanus and rabies may also be accomplished by appropriate means. The recommended procedures are described under the sections on the individual diseases.

**Quarantine.** Quarantine has not been effective for the control of contagious diseases. Early periodically stimulated immunization against the preventable diseases, diphtheria, pertussis, poliomyelitis and smallpox, is accepted as a far more positive control measure.

Chickenpox, mumps, rubella and measles are contagious before the disease is usually recognized, and, in addition, quarantine, if it were effective, would not be practical because (1) active immunity cannot be produced artificially, (2) these diseases are milder in childhood than among adults, and (3) complications which cannot be controlled by available therapy are uncommon.

**Rheumatic Fever.** Rheumatic fever is a recurrent disease of childhood, initial and subsequent attacks of which can be prevented by early and effective treatment of beta-hemolytic streptococcal infections with penicillin (see p. 904).

**Dental Caries.** Dental caries is the most widespread health problem during childhood years. Significant primary prevention can be accomplished by restricting the amount of refined sugars in the diet, by periodic topical application of sodium fluoride to the teeth and by fluoridation of community water supplies (p. 626).

#### PREVENTION OF NUTRITIONAL DISORDERS

In childhood there is a need for food to support growth in addition to that for energy and

for repair. The normal, healthy child usually will select an adequate diet for energy, repair and growth if free choice is possible. Owing to parents' lack of knowledge, cultural patterns, economic restrictions or certain behavior problems, many children do not get the right kind of diet. Serious illnesses can be prevented by making sure that children get sufficient calories and adequate protein, vitamins and minerals. The diet may be considered satisfactorily balanced when the calories are derived approximately as follows: 15 per cent from protein, 60 per cent from carbohydrate and 25 per cent from fat.

Nutritional deficiency diseases are preventable. Parent education in simplified dietetics is a necessity. All the dietary essentials can be obtained from natural foods except vitamin D, which must be given as a supplement, either in a separate vehicle or in fortified foods. Occasionally, supplementation of the diet with other vitamins is necessary to prevent the development of specific deficiencies.

In many localities the problem of undernutrition is less common than that of *obesity*. The prevention of overnutrition is properly an objective of preventive medicine because of the high morbidity and mortality attributable to this condition in later years. The causes of obesity may be psychologic, cultural, economic or, rarely, endocrine. The common denominator etiologically is the intake of more calories than are needed. Prevention, which is far easier than cure, is dependent upon early detection of those factors in the child's environment or personality which predispose to obesity. Sometimes instruction about nutrition and counseling about the causes of obesity are sufficient. In some instances psychotherapy is required.

#### THE PREVENTION OF ACCIDENTS

Infectious diseases and nutritional disorders can be controlled by specific measures. Childhood accidents, on the other hand, are a major problem (Fig. 23) and comprise a challenging field for preventive measures. Accidents now are the leading cause of death in all ages of childhood after the first year, and their relative importance steadily increases as other health problems come under control. Though mortality resulting from accidents is decreasing, the decline is slow compared with that of other causes of death and disability. About 12,000 children under the age of twelve die each year from accidents. Mortality statistics are not a valid index of the problem, however, for it is estimated that

each year 50,000 children are crippled and almost 2 million incapacitated for some time by accidents.

Accidents occur in many situations—in the home, in the street, at school, on the playground. The accident rates among infants and preschool children are notably high (Figs. 24, 25). The majority of accidents in each group occur in the home (Fig. 24). Physicians have the opportunity to help parents anticipate and understand the common hazards of early life and thus provide some "immunity" against accidents.

As the child grows older he becomes increasingly able to take personal responsibility for his safety. Accident prevention in childhood must be based on (1) parents' understanding of the typical behavior and interests of children at various stages of their development so that dangerous situations can be avoided, and (2) parents' appreciation of the wisdom of allowing many of their children's activities to take a natural course for the benefit of experience even though a mildly painful result is clearly foreseen. Real danger calls for prompt protection, but there is value in repeated experiences which teach the child to look out for his own safety.

Certain accidents occur more commonly at one age than another. Scalding burns and falls are common in the second year of life, when children are beginning to walk about the house. The curious, active two-year-old

FIG. 23. Decline in accident rates compared to disease. (Used with permission of Wheatley and Kasey, Metropolitan Life Insurance Company, New York, N.Y.)

FIG. 24. Incidence of accidents according to locality and age group. (Adapted from A. C. Smid and G. B. Logan. Used with permission of the authors. *Minnesota Medicine*, 39:394, 1956.)

FIG. 25. Causes of accidental death in Ohio, 1955. Suffocation is rarely a cause of death in infancy; there is much evidence that most deaths attributed to it are the result of clinically nonmanifest infections (see p. 351). (From information supplied by Division of Vital Statistics, Ohio Department of Health.)

is particularly liable to find and ingest poisonous substances, to have lacerations and contusions from falls and, if there is unguarded opportunity, to fall in water and drown. The three-year-old who can run, jump and climb is most likely to suffer from falls and burns and to be injured when playing near motor vehicles.

Older children are most likely to have accidents attributable to drowning, bicycles and automobiles. Therefore the physician should urge parents to teach their children to swim,

ride bicycles safely and, at the proper age, to drive automobiles skillfully. Such a role is as significant for physicians as are activities for immunizations and good nutrition.

## SECONDARY PREVENTION OF DISEASE

**Controlling the Progression of Chronic Disabilities.** Children whose optimal growth, development and well-being are retarded by chronic handicaps can benefit from measures aimed at preventing the progression of their

ailments and improving their general condition. This is the realm of secondary prevention of disease.

For satisfactory control of chronic disorders early detection and treatment are imperative. Since many such diseases or handicaps are not recognized in the primary stages by children themselves or by their parents, reliance for early detection cannot safely be based on waiting for the parent to seek medical help. Some recognized disabilities, moreover, have become so accepted that medical attention is not always sought. Despite these obstacles, the chances of early detection have increased steadily with improved programs for the appraisal of children's health. Two distinct but related mediums for routine health supervision are the *child health conferences* ("well-baby clinics," "well-child conferences") and *school health programs*.

## DETECTION OF DISEASE, AND HEALTH EDUCATION

**Child Health Conferences.** The many opportunities for preventive medicine and promotion of optimal growth and development have stimulated the development of routine health supervision of infants and children in physicians' offices or in community clinics. When the patient's economic level and the physician's time permit, individual health conferences are preferable to public clinics, since the same physician can supervise the child in health and in illness. When physicians' services are largely engaged by sick children, it is desirable to have community child health conferences planned and operated jointly by practicing physicians and public health authorities. In either case the objectives are the same: assuring optimal health for the child and helping parents to do the best possible job in carrying out their responsibility for their children's health.

The usual program of health supervision in child health conferences includes (1) medical appraisal of the child's growth and development, physical health and personality development; (2) advice about feeding schedules and practices; (3) immunization against the common contagious diseases (see p. 141); (4) guidance for the parents which should consist in a discussion of the results of the current examination, a description of the type of behavior and growth they can expect in the immediate future and full opportunity for them to ask questions. The physician who carries out the child health conference must

be familiar with the various resources in his community for health and welfare.

Such simple laboratory procedures as routine urinalysis, hemoglobin determination, serologic tests for syphilis and periodic tuberculin testing during early childhood are included in child health supervision.

A desirable schedule of health conferences during infancy and the preschool years is as follows:

Birth to six months . . . . .	every month
Six months to one year . . . . .	every two months
Second year . . . . .	every four months
Two to six years . . . . .	every six months

**School Health.** The term "health program for school-age children" is preferable to "school health." This designation indicates that school health is but a part of the over-all community plan for child health, which should begin in the prenatal period and continue throughout the school years. When the child enters kindergarten or first grade, the school becomes a third party, joining parents and physicians concerned with the health of the child. The need for school personnel to be assured that every pupil has attained his optimal health for learning and for school activities is understandable. Thus teachers should know about any physical handicaps of a particular child so that, if necessary, individualized activities can be planned, as in physical education, recreation and manual arts.

The main purposes of a health program in schools are to maintain the health standards of the school environment, to provide health instruction and to cooperate in maintaining and improving the health of individual children. The school environment includes lighting, heating, ventilation, toilet facilities and playground equipment. Health services such as physical examinations, first-aid procedures and screening tests should also be included in the health program. Health services within the school should not replace the child's relations with his family physician, and there should be special effort to motivate parents to seek medical attention when needed. School physicians and family doctors can, by cooperative planning with school authorities, integrate the school's interest in child health with health services for children elsewhere in the community.

**Screening Tests.** Though prolonged diagnostic health examinations and medical treatment are not feasible in schools, the assemblage of children is ideal for utilizing

screening tests to detect those children presumably in need of medical care. Many important health problems of school-age children are asymptomatic and difficult to detect in the early stages by the classic "look-feel-listen" type of health examination. Discovery of nutritional disorders, growth failure, faulty hearing and visual disturbances, all of which require medical diagnosis and treatment, can be accomplished by simple screening tests in the physician's office or in schools.

Screening tests especially adapted to the health problems of school-age children are tests for visual function, hearing tests, measurements of physical growth, hemoglobin determination, urinalysis for sugar and albumin, appraisal of speech, blood pressure determinations, tuberculin skin test and scalp examination by Wood light.

The *visual acuity* (see also p. 1331) of children should be tested at intervals of not more than two or three years. Usually faulty vision is not known to the child or his parents. *Myopia*, the most common refractory error of older children, can be discovered by using the Snellen E Chart.\* The chart should be illuminated by 10 to 12 foot-candle light, obtainable from a 50-watt bulb in a floor lamp or a 150-watt Mazda spotlight. Charts with built-in illumination are available. The child should be exactly 20 feet from the chart during the test. Children under eight years of age should be expected to have 20/30 vision in both eyes, and children eight years and older, 20/20 vision; poorer vision requires examination by an oculist.

Far-sighted children usually pass the Snellen test, but they can be detected by the "plus-sphere" test. A convex lens of plus 1.50 diopters is held a short distance in front of the child's eyes. A child who has clinically significant *hyperopia* will be able to read the symbols on the chart as well through the lens as without it, since he relaxes his usual over-accommodation to compensate for the convex lens. The vision of a child who is not hyperopic is blurred by the plus sphere because he cannot compensate for it.

Latent ocular muscle imbalance, or *phoria*, often can be detected by the "cover-test," in which the child first fixes his vision on a distant object, and then has one eye covered by a card. When the card is removed quickly, the examiner looks for movement of the eye as it again fixes on the object. Normally,

fusion is not lost when one eye is covered. Noticeable movement of the eye immediately after the card is removed is a sign of *phoria* and merits referral to an oculist.

*Strabismus* is usually detectable by observation and, of course, demands prompt referral to an oculist.

Between 5 and 10 per cent of children have significant *impairment of hearing* (see also p. 766), often unrecognized by them. The pure tone audiometer, which detects loss of hearing at octave levels from 250 to 8000 vibrations, is the only reliable method for testing acuity of hearing. The usual screening test is carried out by setting the intensity at 15 or 20 decibels and testing each ear separately. A child who cannot hear tones of every frequency at an intensity of 20 decibels or misses two tones at an intensity of 15 decibels should have an otologic examination and an audiogram. The audiometric test can be given to children of five years and older. The screening test should be repeated at intervals of two to three years; when this is not feasible in school surveys, priority should be given to children in the third or fourth grade.

*Measurements of physical growth* serve two purposes as screening tests: to detect children whose measurements are extremely distant from the mean and those whose growth progress from one examination to another is not within the expected range. Such children should be singled out for special examination to determine whether a health factor is responsible for their status.

*Urinalysis* to detect glycosuria, albuminuria and abnormal cells and casts should be carried out periodically. By using reagents which do not require heating to test for sugar and albumin, these examinations can be performed away from a clinical laboratory.

*Speech difficulties* (see also p. 91) are common during school years and may have lasting effects on personality development. Early detection of lisping, stuttering, nasality and defective speech associated with cleft lip and cleft palate is important so that the child may have the benefit of prompt study.

The determination of *blood pressure* (see also p. 822) is a screening test which can lead to presumptive detection of some types of congenital heart disease, renal disease and certain endocrine abnormalities. Determination of blood pressure is invalidated unless a cuff of proper width is used; one that is too narrow leads to falsely high readings. Recommended widths for cuffs at various ages are as follows:

\* Obtainable from most optical supply firms and from The National Society for Prevention of Blindness, 1790 Broadway, New York 19, New York.

for children under one year of age, 2.5 cm.; for children one to four years, 5 to 6 cm.; for children four to eight years, 9 cm.; for most children over the age of nine years the cuff designed for adults (12 cm.) may be used.

*Tuberculin skin testing* of children (see also p. 461) by the Vollmer patch test or, preferably, by intradermal injection is recommended to detect those who should have roentgen ray examinations and as an aid in finding open cases of tuberculosis among adults who come in contact with the child.

In areas where *ringworm of the scalp* (see also p. 1292) is endemic or where cases have been recently discovered, children who have not reached puberty should have their scalps examined periodically with a Wood light (ultraviolet light passed through a special nickel-oxide filter).

**Health Education.** Since there are no natural motivations to seek preventive services, health education of the public is essential for the optimal development of preventive medicine. Such education may be carried out by schools and official health agencies or by other community organizations. It may be effected by direct or formal teaching and through experiences. In schools health education is usually a required subject at various levels of the curriculum. The factual content of such courses needs constant revision to keep it abreast of current knowledge.

Physicians and nurses have greater opportunities for meaningful teaching of health than do educators. Sufficient time should be taken during a medical examination or health conference to explain the health procedures and to discuss the results of the examination and the reasons for suggested treatment. Unfavorable attitudes, which may

be lasting, result from hurried, incomplete examinations and inadequate explanations.

# ADOLESCENCE

## PHYSICAL ASPECTS OF ADOLESCENCE

Adolescence, "the process of development from childhood to manhood and womanhood," is considered here the period beginning with the appearance of secondary sex characters and terminating with cessation of somatic growth. Among the laity "puberty" is synonymous with the first menstrual period in the girl. A point developmentally corresponding to this in the boy is the time of

appearance of spermatozoa, which is difficult to determine. It is said to coincide with the development of curly pubic hair. The "pre-puberty" or "pubescent" period refers to that of accelerated growth and the appearance of secondary sex characters which precedes puberty. Separate consideration of adolescence is justified only to the extent that this period differs from the other phases of growth

by characteristics which make the approach to its clinical problems unique in pediatrics.

Chronologic age as a point of reference ceases to be useful at this time, if indeed it ever was (Fig. 26). The problems of the thirteen-year-old girl come into focus only when we know whether we are dealing with a prepubescent or pubescent girl, or with one whose menarche may have been one, two or three years previous. The need for assessment in terms of physiologic age was emphasized by Crampton more than forty years ago, but there have been few changes in the handling of school difficulties related to this factor. Adolescence is a period of growth with rapid changes in rate in sharp contrast to the fairly steady rate of the several years that precede it; these changes can be predicted and evaluated only against a scale of physiologic age. The fluctuant metabolism, the food requirements, the scholastic capacity and even morbidity can be discussed only in terms of physi-

ologic achievement. Actually, a school class of thirteen-year-old girls could include examples of eight different physiologic ages (Fig. 28 and Table 29).

The physical, emotional and scholastic problems of the girl and the boy diverge so sharply as to require a totally different set of standards for assessment at this period after a sexless phase when they could be considered in large measure on the same basis. The thirteen-year-old girl who has achieved puberty has progressed at least two years further toward maturity than a boy of the same chronologic age; she feels as if it were five.

So great is the individuality of the pattern of growth and development of the period that attempts at generalization break down in the presence of specific problems.

In private schools where individual curriculums are possible, physical and emotional problems resulting from the discrepancy between physiologic and chronologic age ma-

be minimal; this cannot be obtained in the average public high school. Only when growth studies permit an early prediction during the preschool years of the expected growth schedule will it be possible to discard the present rigid plan of starting all children in school at an arbitrary chronologic age and to substitute a plan that will take into account physiologic and mental age. Meanwhile the adolescent will continue to have problems conditioned by the present system. The effect of such frustrations on the psychiatric

problems of adult life is conjectural, but it must be considerable.

Differences in the rates of development of the two sexes are well enough established to take them into account in educational planning. In a "readiness for reading" test the girl is advanced at least a year over the boy. This difference becomes greater as puberty is approached, and scholastic accomplishment is comparable in the two sexes only when both have passed through puberty; the boy accomplishes this about two years later than

FIG. 28. Shuttleworth's curves of annual height increments to show how strikingly different patterns plotted against chronologic age become reconciled against a physiologic age scale. Annual increments in standing height of 8 groups of girls who attained menarche at different ages (see Table 29). The curves are arranged so that the points corresponding to the menarcheal age are on the same vertical line. The 3 horizontal grid lines indicate, respectively, zero growth per year, one ninth of the average growth from age 8 to 17 (SLG), and two ninths of the average growth from age 8 to 17 (2 SLG).

the girl. To wait until puberty to consider the problems posed by this difference would seem short-sighted.

The individuality of the pattern of growth must also be borne in mind. Figure 27 shows a boy whose time schedule is slower than average. Physically, he is sufficiently different from his chronologic peers to cause concern to parents who may seek advice concerning endocrine therapy to accelerate his development. The need to explain the normal physiologic variations is a constant one in dealing with parents of adolescents, who should be reassured that endocrine therapy is not indicated in such circumstances. The comments of Frank in this regard are especially pertinent.

We cannot expect the individual boy and girl to meet these requirements (the tasks of life and the demands of maturation) effectively if in our various programs and practices in the home, in the school, the clinic and hospital, and in the youth organizations and elsewhere, we persistently deny the basic, ineradicable differences among individuals and impose upon them the tyranny of the norm. Perhaps in no other period except old age is there a greater need for the clinical approach which explicitly recognizes this individuality and mediates both the re-

quirements and the needs of adolescents in accordance with the peculiar make-up and capacities of the individual boy and girl.

**Nature of Growth.** Growth in man does not follow a straight line, but consists in a series of alternating rapid (fetal, infantile, prepuberal) and slow periods, the curves revealing distinct waves roughly likened to three S-shaped curves. The third curve shows a slight lag about three years before sexual maturity, followed by a sharp acceleration, which terminates in—and is apparently conditioned by—the attainment of sexual maturity. This final spurt is followed by a deceleration. Growth during adolescence is a function of physiologic rather than of chronologic age, as demonstrated in the charts of Shuttleworth, by the fact that the growth patterns of girls maturing at ages varying from ten to seventeen years can be superimposed only if chronologic age is ignored and the plotting is done in terms of physiologic age, using years preceding and following puberty as the time scale. This fact is basic to an understanding of many of the normal physiologic variations at this age period which create deep concern in the patient and the parent.

Transition from one growth curve to another, accompanied by changes in metabolism, may be fraught with considerable danger to the growing child. The sharp increase in the incidence of tuberculosis during adolescence and the steadily mounting incidence of rheumatic fever up to puberty, with a decline following it, suggest that reaction to disease is handicapped by the added demands of growth during this period. It is believed that much of the difficulty can be explained in terms of nutrition and that adequate provision for dietary requirements peculiar to this period may be a main factor in the resistance to disease.

In graphs showing the average yearly increments of height and weight (Fig. 8, p. 14) the time of maximum growth of the two sexes is separated by about two years. Weight increments increase steadily from the age of five years, with an acceleration in the prepuberty years. On the average, the girls' weights are overtaken by those of boys and passed in the thirteenth year. Data such as these have the limited usefulness of generalization and need to be individualized against a physiologic achievement scale. For this purpose the Wetzel grid is helpful. There are striking differences in the growth patterns of the two sexes, as evidenced by broadening

of the pelvis in the girl and of the shoulders in the boy in the year of maximum growth.

**Metabolism.** The basal metabolic rate shows a relative decrease from early infancy until the termination of growth. This trend is interrupted by a relative increase during the two years of accelerated growth that precedes puberty. Determinations made at six-day intervals in the prepuberty and postpuberty periods demonstrate this pattern, though the phenomenon may be obscured by averaging the data rather than plotting them and by the use of chronologic rather than physiologic ages. It is probable that this normal physiologic tendency to an elevated metabolic rate in the prepubertal period is related to the increase in hyperthyroidism during this age period. It explains, too, the sharp increase in the requirements for calories and insulin in the diabetic child as he approaches puberty.

**Calcium and Nitrogen Storage.** Studies of the retention of nitrogen and calcium throughout adolescence reflect, as might be expected from the growth patterns, extremely high retentions preceding menarche and frank depressions associated with the decelerating phase of growth following it. With an adequate intake of protein and calcium and in the absence of disease this depression does not reach the point of negative balance; but with an inadequate diet it may readily do so.

The extent of these differences is indicated in data on three normal girls on whom balance studies were obtained for several months preceding and following menarche. With dietary intake constant, nitrogen retention fell from 3.14 to 1.75 gm. a day; calcium, from 495 to 352 mg. a day. Retention of both substances continues to decline with the decrease in the rate of growth.

**Dietary Requirements.** What is an adequate dietary intake during this age period? In the diabetic child, by using satisfaction of appetite and normal growth as criteria, the caloric requirements can be determined by multiplying Wetzel's predicted basals by 1.9. A much better correlation is obtained in relation to physiologic than to chronologic age (Fig. 30). Though in the diabetic child and the institutionalized patient such estimates may serve a useful function, they are not practical in the average home where the dietary intake is governed by appetite and by economic circumstances. In view of the frequency with which one hears the statement from the overcautious mother, "Of course, I don't allow her to have much meat," it would seem that the provision for protein

and calcium requires definite direction. When the diet is adequate in calories, as judged by satisfaction of appetite and normal growth, 15 per cent of the total calories should be derived from protein in order to maintain a consistently positive nitrogen balance. The adolescent child requires 90 to 120 gm. of protein a day, which can be supplied by one quart of milk, one egg and two slices of bacon, one serving of cheese and a liberal serving of meat at the principal meal. The author has found that the child's appetite for protein is a reliable guide to avoid excessive intake. When an attempt was made to explore the upper limits of nitrogen storage, protein intoxication was frequently encountered when the child's refusal was ignored. The converse, however, is not true. The self-selected diet of the adolescent frequently slights protein in favor of carbohydrate and

FIG. 29. Metabolism at puberty. The basal metabolic rate is fluctuant in this well trained subject, the range of basal calories being 200. There is a tendency to high rates just preceding and to lower rates following the menarche.

With intake constant, retentions of both calcium and nitrogen were high preceding and depressed following the menarche. This is in keeping with what might be expected from the rates of growth at this time.

## CALORIE INTAKE BY THE DIABETIC

FIG. 30. Caloric intakes of diabetic children by age and sex, illustrating sharp increases with the accelerative phase of growth in the prepubertal and adolescent periods and decreases during the decelerative period of growth.

fat. There is, therefore, indication for defining the protein portion of the dietary intake.

The adolescent's requirement for calcium is approximately 1.3 gm. A quart of milk a day is necessary during the period of accelerated growth, but it is doubted whether this much is required in subsequent years. For the obese child on a reducing diet the proportion of calories derived from protein should be increased to 20 per cent, and, if the intake of milk is less than a quart a day, the calcium deficit should be supplied by a calcium salt. The usual 1-gm. wafer of dicalcium phosphate contains 0.2 gm. of calcium. Vitamin D (about 1000 I. U. per day) is essential for adequate absorption and retention of calcium during the growth spurt of adolescence.

**The diabetic adolescent.** As might be anticipated from the pattern of growth, the caloric intake of the diabetic child increases rapidly during the accelerative phase, declines during the decelerative phase, and stabilizes when growth has terminated. Fig. 30 illustrates these changes in a group followed into adult life.

Vascular complications made their first appearance in this group only after the dia-

betic state had existed for more than eleven years. Examination of the fundus, determination of blood pressure and urinalyses for abnormalities other than glucose should be routine in this age group. In our experience there was good correlation between the development of these complications and the degree of control of the diabetes.

**Tuberculosis.** The sharp increase in mortality from tuberculosis during adolescence and the fact that this increase is manifest in the girl about two years before it is in the boy suggest that something inherent in the metabolism of this period has an undermining influence on a quiescent lesion or on susceptibility to a new infection. In 1000 children with apparently healed primary lesions who were removed over a period of twenty years from homes where there was active tuberculosis to tuberculosis-free foster homes, twenty reinfection lesions appeared after the break in contact. Two thirds of these were in girls, the majority of whom were between eleven and seventeen years of age. The mean menarcheal age was a year earlier than average. Metabolic studies carried out during the course of their infections showed a striking correlation between the healing of disease and the retention of nitrogen and calcium. Unin-

errupted healing was accompanied by strongly positive balances, whereas spread of the lesion was preceded and always accompanied by negative balances (Fig. 31). It would seem that anything which might be a factor in the production of a negative balance (inadequate diet, deviations in basal metabolism, acute or chronic infection or too great an expenditure of energy) may play a role in the flare-up of disease at this time. Supervision of the child with a quiescent tuberculous lesion necessitates provision in this age period for a diet especially adequate in protein, calcium and vitamin D. Thyroid function should also be evaluated. A record of the time spent in school and extracurricular activities will often reveal an expenditure of energy incompatible with the demands for normal growth and development, and, as a corollary, for the integrity of the healed lesion.

**Osseous Development.** In general, epiphyseal closure marking the completion of skeletal growth coincides with the attainment of sexual maturity and correlates better with physiologic than chronologic age. Growth in the extremities ceases before that of the vertebral column. Flory noted the relation of the appearance of the sesamoid bone at the distal end of the first metacarpal to maturity; he observed no girl who menstruated before its appearance. Maresch believes that when fusion of the capitulum of the humerus to the shaft has occurred, the main growth spurt is over, and, in the girl, menarche might be predicted in the following year.

**Osseous disturbances.** The striking changes in growth rates before and after puberty reflect changing rates of speed in osseous growth and probably play a prominent role in the bone disturbances of this age period. Park and others have called attention to definite rachitic changes in this age group.

Perhaps the outstanding osseous disturbance of adolescence is the so-called slipped epiphysis. The etiology of this condition is still a matter of conjecture. The average age in the recorded cases is twelve years for girls and fourteen to fifteen years for boys, ages corresponding to the phase of maximum growth. Characteristically, the patient is tall and heavy, but not the typically fat child. The author has studied the calcium balances of seven children with this condition. Five of them were studied postoperatively, so that their poor retentions might have been the result of the trauma of surgery and of inactivity at bed rest. Nevertheless, in three of

them the administration of vitamin D increased the retention of calcium. Howard observed similar results in children with fractures. Administration of thyroid extract and

FIG. 31. Metabolism at puberty with spread of a tuberculous lesion of the reinfection type. A girl 13 years of age with an apparently minimal tuberculous lesion of the reinfection type, while being studied to determine nutritional requirements during the adolescent period, gained steadily in weight during the first 45 days, but showed a positive nitrogen balance only with high intakes of nitrogen. The basal metabolic rate was +2 (+5 by Talbot height standard), but it declined gradually. The negative balance at the menarche could be attributed to a diminished intake, but immediately after the menarche the balances were negative on amounts which before the menarche gave positive balances. In the twelfth 9-day period a rise in basal calories occurred from 1409 calories to 1655 (—5 to +11 Boothby; —2 to +18 Talbot), and at this time there was detected a frank spread of the tuberculous lesion which required therapeutic collapse of the lung.

Though cause and effect are difficult to separate, the author's favorable experiences (as measured by gain in weight and by retention of calcium and nitrogen) in the management of children with minimal tuberculous lesions by simply maintaining them at bed rest leads him to conclude that menarche in this girl resulted in an untoward effect on metabolism which favored spread of the tuberculous lesion. Roentgenographic evidence of extension of the lesion was already present when the peak metabolic determination was obtained.

testosterone reduced the retention of calcium. Any method which would effect a normal retention of calcium would seem to offer a contribution to prevention and therapy. It is suggested that this type of child should receive larger than average intakes of calcium (at least 1.5 gm.) and vitamin D (2000 units) during the preadolescent spurt in growth.

Vertebral epiphysitis occurs in the phase of decelerating growth, at the time when leg length has reached its limit, but there is continued growth of the vertebral column.

**Anemia.** There is a significant increase in hemoglobin between the ages of eleven and fifteen years. In the prepuberal period it is the same for both sexes, but, after puberty, the female level is 2 gm. below that of the male level. In the older literature "chlorosis of puberty" was described as a common condition. Though its incidence is now much less, hypochromic anemia occurs sufficiently often in this age period to be considered a cause of fatigue and fainting.

**Thyroid Disturbances.** Most instances of hyperthyroidism among children occur after ten years of age during the prepuberal and early adolescent periods. This relative increase reflects the instability of basal metabolism during these age periods. Mild hyperthyroidism is encountered which, with high caloric diet, elimination of strenuous school schedules and the administration of iodine, seems to terminate with the attainment of sexual maturity. The management of severe disturbance requires more active therapy (p. 1173). Since a fall in the basal metabolic rate is anticipated after menarche, the medical management of hyperthyroidism should be more effective at this age than at other age periods.

In the author's experience, which may be influenced by residence in a goiter belt, hypothyroidism is common in the period just following the onset of sexual maturity. The features which have suggested it have been chiefly (1) delay in growth and development, (2) mental retardation, (3) fatigue, and (4) menstrual disorders. The effect of thyroid at this period is anabolic, and administration of thyroid extract to correct a deficiency will result in gains in height and weight. Hypothyroidism is rarely a factor in the obesity of adolescence, in which basal calories are usually elevated. Hypothyroidism is often suggested because progress in school is unsatisfactory. One of the effects of therapy is an increased span of attention. The menstrual disturbances include scanty or profuse flow

and too short or too prolonged intervals between menses.

There is lack of agreement on the dosage of thyroid extract for hypothyroidism at this age. Administration to "tolerance" would seem to be unjustified, since with such amounts the initially sought anabolic effect on nitrogen and calcium is reversed. It is rarely necessary to use more than 90 mg. of U.S.P. thyroid extract for even the severe cases. When there is an inadequate response to this dose, the intake of protein should be investigated, or, when the initially low blood pressure is not elevated, the adequacy of adrenal function should be determined.

**Obesity.** The subject of obesity is discussed elsewhere (p. 354). The author agrees with Bruch that deficiency of the thyroid is rarely a factor. When the basal metabolic rate of a group of children was determined by Wetzel's standard, the average correction in obese children was 20 per cent. Thus, when a calculation on the conventional surface area method was recorded as -20, the rate by the Wetzel prediction would be normal. The control of weight of greatly obese children by a diet high in protein, calcium and vitamin D, but low in calories, is indicated. In addition, investigation of the behavior problems common in this group is an integral part of the management. Some of these children will have hunger contractions at more frequent intervals than usual, probably as a result of their more rapid utilization of glucose. The high protein-low carbohydrate diet, particularly for the morning meal, is useful in allaying this symptom.

**Secondary Sex Characteristics.** In the order of their appearance these are, in the girl, (1) increase in the transverse diameter of the pelvis, (2) development of the breasts, (3) change from alkaline vaginal secretion to a strongly acid one, (4) appearance of pubic hair and (5) of axillary hair. The first menstrual period tends to occur between the appearance of the last two factors.

In the boy the puberal phenomena make their appearance over a two-year period in the following order: (1) increase in size of the testes and penis, (2) swelling of breasts, (3) appearance of pubic, axillary and facial hair, (4) change in the voice, and (5) production of spermatozoa. This last item is not practicable of demonstration, but is considered to coincide with curliness of the pubic hair.

**Sex Hormones.** That puberal development is subordinated to skeletal growth for a period of years is evidenced by the fact that though

the androgens, or male sex hormones, and the estrogens, or female sex hormones, both show an increase by about seven years of age in both sexes, the great increase does not occur until the prepubertal period.

**Hypogenitalism in the Male.** (See p. 195.)

**Menstruation.** American girls have an average age at onset of menstruation of thirteen years, the range being between eleven and fifteen. Only 3 per cent will begin earlier and 3 per cent later. From growth records the onset can be predicted as likely to occur following the maximum increment of growth in height; except in those who menstruate early, it is likely to occur in the same year. Probably because the cycles are anovulatory, irregularity in interval can be expected in the first year. When irregular intervals or a prolonged or scanty flow persists into the second year after menarche, the factors discussed below should be investigated.

**Menstrual irregularities.** Most complaints of adolescents and their parents that relate to menstruation stem from failure to appreciate one or more of the following: (1) the wide range of age at onset of the menarche; (2) the normality of irregularity in the first year; and (3) the fact that a normal cycle is more closely related to general factors of health than to any specific hormonal defect.

In a study of fifty girls with menstrual disturbances serious enough not to be dismissed as "physiologic variants" the following factors seemed to play some role in etiology:

1. **NUTRITION.** There were five examples of malnutrition and five of obesity. The correction of either state may be all that is necessary to influence favorably the menstrual irregularity, but this may not be simply a matter of diet. One fifteen-year-old girl who had failed to menstruate for six months was profoundly malnourished because of a caloric intake of only 900 calories. Her basal metabolic rate was minus 25. She was attempting school work far beyond her capacity and had become depressed by her inability to keep up with it. As a result she had anorexia of nervous origin; the depressed metabolism was a function of her low intake. Only when her school problems were adjusted did she eat normally, and, with an adequate intake, her menses were resumed.

In obesity of adolescence a low calorie-high protein diet will effect a loss of weight. It is important to inquire why a child is overeating, since few children eat excessively except as a solace for social inadequacy. Correction

of the underlying emotional difficulty constitutes the real solution.

2. **EXERCISE.** The teen-age girl seems to go to extremes on activity; there is either too much in the way of athletics, or, in her concern over her scholastic curriculum, she gets no exercise at all. Each may be expected to influence the menstrual cycle, presumably through fatigue on the one hand, and through the depression of metabolism that results from inactivity on the other. In an industrial plant employing a large number of teen-age girls as office clerks a study was made of absenteeism resulting from dysmenorrhea. One group of girls was placed at complete bed rest during the menstrual period, whereas another group participated in active sport (basketball) followed by hot and cold showers. There was a significant shortening of the duration of the complaint in the latter group. Ewing eliminated the complaint in 50 per cent of 500 girls with a regimen of postural correction and exercises. The Mosher exercise, consisting in contraction and relaxation of the lower abdominal muscles independent of breathing, was used. He also stressed the need for correction of constipation.

3. **PSYCHOGENIC FACTORS.** Such disturbances seemed to play a causative role in 12 per cent of our series. The girl who is "straining her I.Q." in a discouraging attempt to do schoolwork beyond her capacity and the girl whose overambitious parents permit a full school schedule to be supplemented with hours of music practice and social engagements may show evidence of strain by a disorder of the menstrual cycle. A physician at a woman's college reports that during the first semester of the freshman year she expects a majority of the class to have an interruption of the menstrual cycle; this is attributed to two main concerns: attainment of passing grades and acceptance by a sorority.

4. **THYROID DISTURBANCE.** The normal tendency for the basal metabolic rate to be elevated before and depressed after the menarche results in a number of instances in which this physiologic change is extended to abnormal levels. Within the limits of physiologic variation the changes can be ignored, but, when they extend beyond these limits, the disturbed state will be reflected in an abnormal menstrual cycle. We have observed mild degrees of hyperthyroidism, evidenced by nervousness, sweating, elevations in pulse rate and pulse pressure, and increased metabolic rate, which responded to treatment with rest and iodine, which, in turn, was followed

promptly by appearance of the first menstrual period. In the group of fifty girls with menstrual disturbances the metabolic rate was determined in thirty-four. It was elevated in ten and depressed in eighteen. Of the latter, sixteen were benefited by therapy with thyroid extract. A low metabolic rate is not equivalent to the diagnosis of hypothyroidism, and a depressed rate may be observed with an inadequate intake of food.

5. ORGANIC LESIONS. In the study there were five girls who had organic lesions: two with cystic endometritis, two with ovarian cysts and one with an adenomyoma. Though the majority of menstrual disturbances in the first few years following menarche reflect general disturbances capable of being evaluated and treated by the pediatrician, no case should be followed long without gynecologic consultation. To resort to it routinely may result in psychic trauma and may defeat management which otherwise would require only a common-sense direction of activities.

## PSYCHOLOGIC ASPECTS OF ADOLESCENCE

Adolescence is a long and indeterminate period of growth and development in which the young person experiences profound changes in physical development, in attitudes, in conduct and in the organization of his total personality. He does this without divesting himself of many of the characteristics which have become part of him in his development through childhood. Something of every stage of his emotional growth remains as he approaches maturity. During adolescence adjustments must be made which are not only satisfying to the child, but which must be acceptable to the community. Although he normally reverts on occasion to

earlier and less responsible ways, for the most part he proceeds on new terms with himself and his family. The adolescent may be regarded as striving for self-realization as an adult, being both stimulated and threatened by profound physical changes and consequent thoughts and feelings, and by conflicting demands of a world not certain whether to treat him as a child or a young adult.

A child who has grown to puberty deprived of security through the affection of parents, friends and others is likely to show neurotic patterns during the normal conflicts of adolescence. The child who has been over-restricted is insecure. The adolescent de-

velops best when he has received basic security in the family unit without being enveloped in ties that bind him to dependent relationships. Some attitudes and behavior which resemble symptoms of maladjustment in childhood or adulthood may be said to be normal in adolescence. Any adolescent on occasion finds the demands of his radically changing world too much to deal with; accordingly he fluctuates between extremes of behavior. In adolescence he manifests independence and self-reliance without the judgment and experience which it is to be hoped he will later acquire.

### PROBLEMS OF PHYSICAL HEALTH

Physical and psychic changes may appear suddenly, especially in girls at the onset of menstruation, or more slowly over a period of a few years. A physical awkwardness often develops which must be sympathetically handled, since it is a source of much embarrassment and emotional strain. Adolescence is characterized by changing attitudes toward self, personal relationships and basic social institutions. It is important for the pediatrician to be aware of the growing child's changing attitudes because they are related to physical changes which appear at this time.

Both boys and girls begin at this time to take a careful interest in clothes and personal appearance. The desire to excel in sports is increased; dancing becomes an important part of existence; social clubs, cliques and "gangs" are formed; clubs, fraternities and sororities are joined; and automobiles, cinema stars and far-from-classical music become absorbing interests. The children become noisy and bouncy and introduce themselves unmercifully into the serenity of the adult's life. Although this behavior may superficially appear to be due to emotional and social growth, it is related intimately to physical development. For example, the adolescent's interest in clubs and in his personal appearance hinges on the feelings and attitudes and the beliefs and misconceptions he has about his physical state. In physical health he is in a somewhat precarious position. He has a greater tendency to metabolic disturbances and is more susceptible to some infectious diseases than he was in the preceding period of development. It is possible that growth processes themselves are attended by feelings of anxiety manifested by physical discomfort and even symptoms of illness. Physical illness also may be the result of the child's effort to cope with his emotional prob-

lems. Such symptoms as anorexia, overeating, aches and pains, fatigue, palpitation, breathlessness, and urinary and fecal incontinence may appear.

When physical illness appears, the adolescent may react to it as if it were a threat to his prestige, to his ability to compete with his peers. He experiences deep anxiety about his physical state; frequently he overcompensates for a physical deficiency by attempting to excel in some other direction of physical exercise, trying to develop a robust physique which will overshadow deficiencies. Occasionally when the adolescent feels at a disadvantage physically, he strives to overcompensate by intellectual achievement. Physical difficulties are often concealed, or the child may have complaints about conditions which he imagines are developing. And yet, while he has a tendency to fear illness and to consider himself potentially sick, he also tries to deny the existence of any such incapacity. The surface complaints which bring him to the pediatrician often are physical. They may or may not have emotional beginnings. Many somatic difficulties in adolescence due to psychologic difficulties have their beginnings during infancy and childhood, being precipitated by stresses and strains of the teen-age period.

It is not always easy to see the interrelationship between the physical complaints and emotional disturbances. There is a high correlation between difficulties in social adaptation and excessive interest in the body. This may be true when an organic lesion exists or when the complaint is merely a somatic correlate of an anxiety state. Such complaints often take the form of hypochondriasis.

A frequent complaint is related to the skin. Acne represents a disfiguring condition to the adolescent, who reacts by withdrawing from social relationships, fearing that his whole future is jeopardized. The attitude of exaggerated concern should attract the attention of the pediatrician, and therapy should be aimed at helping the child with his feelings of concern as well as the acne. If attention is focused merely on treatment of the skin, the acne may disappear, but the child's concern will be directed to other cosmetic conditions.

Faulty nutrition, either real or fancied, excessive fatigue, body aches and difficulties of sleeping should also be considered, not only in a narrow physical sense, but also in terms of the total organism. Poor eating habits may lead to either malnutrition or obesity. The reasons for not taking food are often due to

self-imposed limitations, and overeating as an outlet for feelings of tension may be the cause of obesity. Psychologic concomitants of such chronic diseases as diabetes and heart disease should be sought and considered in planning a medical regimen.

Adolescents with physical handicaps are able to make a healthy personal and social adjustment if in their early life they were given a reasonable economic and emotional security by parents who had accepted them fully in spite of their physical incapacities.

Frequently there are disturbed familial and childhood relationships. Often one or both parents are neurotic, and the child has been reared in an environment lacking the security of normal parental affection. Intense hostile and dependent attitudes develop, and the child takes on pregnancy fantasies and defenses against the possibility of growing to maturity. These young people are extremely disturbed, and the problem is primarily one for psychiatric treatment. The obese child is fat because of an excessive appetite. He usually has anxiety and feels incompetent to enter into the activities of adult life. Overeating represents a regressive reaction with further repression of sexual strivings. The obese adolescent seems to revert to an essentially dependent state, expressing this in a retreat to gratification through the mouth such as he exhibited normally in early infancy and childhood. Here again the psychologic condition is complicated and responds best to psychotherapy.

In both sexes there is concern about breast and genital development. In the girl there is interest in body contour and size of breasts. Frequently girls who feel that they are in danger of becoming too large or who believe that their breasts are unusually big, restrict their dietary intake to an extreme degree.

In the male, concern about penis size and descent of testes is a chief complaint in this age group. Sometimes the anxiety has been projected from the parent to the child and represents the parents' own sexual maladjustment, which now expresses itself in overconcern for their child's development, which may be proceeding in a normal fashion.

### SEXUAL PROBLEMS

Sexuality and interest in sex begin before puberty, although there is an increase in sexual impulse at this time. Infants and preschool children show an interest in all parts of the body, the sexual organs exciting no unusual interest. Soon, however, there is

interest in the genitals because of the pleasurable reactions that follow manipulation, whether this be accidental or deliberate. The preschool child is interested in the genitals of his age-mates and begins to recognize the differences of the sexes. There may be experimental play between children as well as exhibitions of prowess and demonstration of body parts at any age period from now on. With puberty there is an increased modesty which began to be evident around five and six years of age, but is now accompanied by an increased curiosity in the function of his own body and that of persons of the same and of the opposite sex.

Sexual problems may arise at any time in the life of the growing child. They stem, in most instances, from a clash between the pressures and demands outside the child (his family and culture) and his inner urges and drives. The anxiety which is a by-product of such a clash may show itself in a number of ways, one being heightened sexual excitability and excessive sexual manipulation. Shame and guilt are frequent accompaniments of masturbation in the adolescent; these feelings may also be felt about menstruation and nocturnal emissions. Such misconceptions may be abetted by a rigid tradition in the home toward sex. An unusual degree of anxiety may also be focused on the homosexual interest which normally comes during puberty and early adolescence.

The adolescent strives to handle the problems inherent in making a sexual adjustment by various methods. These range from defiance of traditional rules of conduct by promiscuity, to the other extreme of ascetic denial of sex impulses. Promiscuity is fairly frequent and arouses much concern in the public because of its extreme and often delinquent quality. Contrariwise, those persons who have unnaturally repressed their sexual impulses receive scant attention because they are more socially acceptable. This group is probably larger than the group of delinquents and also is in need of consideration.

### SEX EDUCATION

Since sexual development is continuous from infancy through adolescence, it should be clear that there is no special sex education of the adolescent. Sexual education is a process which goes on with sexual development. It is true that questions and problems of sex and sex behavior need to be handled differently at various ages, but sexual education should never be considered merely a matter

giving a child the facts of life at a given age. The sexual orientation of the mature adult results from a synthesis and integration of attitudes and values which as a child he experienced with parents who themselves were mature sexually as well as in other respects. The experiences of being loved and cared for in infancy, of being identified with a healthy father and mother, of living with brothers and sisters, and of playing with other boys and girls, result in a broad education which includes sex education. The adolescent with sexual problems may be helped by discussing them with someone acceptable to him, such as a relative, an educator, a nurse or a physician. Simple explanations will help in the re-education of the person who comes for help, but the greatest helpfulness will come from a relationship with an adult to whom the adolescent may entrust his feelings and in whom he may find a sympathetic and understanding listener, who does not condemn or necessarily condone, and who is held in high esteem by the child.

#### SCHOOL PROBLEMS

Many school problems arise because the child has difficulty in learning or keeping up with a pace which is too rapid for him. The adolescent may have difficulty in making an adjustment in high school because the pace is accelerated over that of the grade school or because of problems of his own which inhibit his capacity to study. For some the period of readjustment is short and transient; for others it is long and in an unsympathetic school system may persist. Occasionally, increased pressure from parents will also add to the burdens at this time. Having a larger body, he is now expected to have a greater efficiency and to be able to participate in many more activities. On the contrary, the adolescent may be less able to meet these new demands. Many school problems could be prevented if educators and parents became aware of the differences of the adolescent not only from his age-mates, but also from his previous self. A school system which attempts to deal with the whole child, not only in learning and teaching, but also in physical, emotional and social development, will combine the forces of the educator, school physician and guidance counselor with the parents in planning school activities. Too frequently the child straining for academic achievement is prevented from full development of abilities which are within his reach, owing to the pressures of school and family. The physi-

cally or intellectually handicapped child suffers when his intellectual limitations are not recognized and when his parents and the school do not face the problem realistically.

#### THERAPY

Treatment of the problems of an adolescent entails an understanding which can be achieved only by separate interviews with the child, his parents and educators. The adolescent can be helped only when he is willing; he is resistive when he feels that parents or others are coercing him. Any relationship with an adolescent which he initiates or believes he initiates has the possibility of being of therapeutic value. The adolescent at this phase of development is especially sensitive to the personality and attitudes of the adults with whom he has contact. Teachers and physicians even more than relatives are in a position to help the young person at these times, but only when trust and confidence are felt toward them. Accepting an adolescent as a person approaching adulthood rather than as a child will have a good influence on the insecure adolescent. The parent frequently has difficulty in accepting the adolescent on these terms and hence can serve less objectively, in the therapeutic sense, than professional people. The physician who encourages the adolescent to review his life story and permits a discussion of life situations which are disturbing in terms of his family and personal content without assuming the attitudes of the family members toward him will be able to help in the solution of his problems. An occasional physical examination may also serve as reassurance that there is no disease. The pediatrician can help the adolescent further by working with parents and others who are intimately concerned in his day-to-day welfare. The adolescent's concern and feelings of shame about any of the parental characteristics are normal, and in the more sensitive child are a source of much secret conflict leading to rapid fluctuation between rebellion and sudden gushes of contrite affection. A discussion with parents about the reasons for the rebellion and an explanation of the striving for independence and the craving for dependency often help to clear misunderstandings. No advice or regimen will make adolescence easy, but parents and children often may be helped by a therapeutic relationship with someone outside the family in whom each has confidence. The role of the pediatrician may be enhanced if he has taken care of the adolescent since early

childhood, or it may be hindered if the adolescent resents taking help from "a baby doctor."

One important role of the pediatrician is the safeguarding of the adolescent's physical health and growth. Much has already been said of the heavy physiologic demands in this period of development. Evaluation of every disorder, whether psychologic or physical, should include an appraisal of general health, nutrition, sleep patterns and general activity, keeping in mind the metabolic and infectious disorders prevalent in this age period. *The adolescent must be considered a human being rather than a "case study in pathology."* Since physical complaints are frequently the first manifestations of underlying psychologic disorders, the physician is often the first one called upon for help. Hence he is in a strategic position for recognition of the early stages of severe mental illness by interpreting the psychologic undercurrents of the physical complaints. The adolescent's concern about normality may resemble the hypochondriacal state of adults and should make the physician suspect beginning maladjustment. Help at this time may prevent a more severe breakdown later.

In the event that no physical abnormality is found, the verbal reassurance that nothing is wrong, and hence that parent and child need not worry, is usually ineffective. The concern of the patient often reappears if it has been temporarily removed. It is important that the physician not get caught in the position of simply "telling" the adolescent some-

thing or "giving" him something, but rather should permit him to *talk out* and so gain some awareness of the cause of his difficulties and some insight into their origin. This does not mean that educational and vocational guidance and change of oppressive environmental factors should not be offered. The patient should have an opportunity of returning for interviews, but these should not be forced on him. When adolescents or their parents are not reassured by such psychotherapeutic endeavors, one should suspect psychologic difficulty which warrants psychiatric consultation and treatment.

The pediatrician should view his psychotherapeutic task as twofold: (1) the *relief* of immediate problems, and (2) *prevention* of mental health problems through helping the adolescent to adjust not only to his adolescent period, but also to the responsibilities and stress of adult life and eventual parenthood. *The pediatrician has an opportunity in the field of preventive psychiatry not only during adolescence, but also throughout the lifetime of the infant and child.*

# General Factors in the Care of Sick Children

## CLINICAL APPRAISAL OF INFANTS AND CHILDREN

The pediatrician has the opportunity and the responsibility of developing a balanced, comprehensive approach to evaluation of the subtle psychologic components in disease and to the promotion of emotional as well as physical health in the child and his family. For a variety of reasons hospital-trained physicians often tend to rely too heavily upon laboratory data in their evaluation of the sick child. In so doing they may neglect the manifold clinical impressions and behavioral data available from careful observation of the child and of the interactions between parent and child.

For example, flaring of the alae nasi, shallow respirations with expiratory grunting, restlessness, suprasternal and substernal retractions, and visible disturbances of the peripheral circulation may provide vital clues to an impending state of cardiorespiratory collapse in an infant with serious tracheobronchitis in an early but rapidly advancing stage. Such signs may be present on inspection before physical, roentgenographic and laboratory data reflect the gravity of the situation. Failure to recognize the import of early signs often leads to serious consequences which might have been avoided. Similarly, reliance upon the absence of abnormal physical and roentgenographic findings in a three-year-old child with a history of persistent, nonproductive cough may lead to a strenuous and expensive course of laboratory study or to an unreassuring diagnosis of "no disease." More careful observation of the interaction between mother and child and more painstaking investigation of the history might have revealed that the cough had originated with a mild and transient coryza at the time of the birth of a new sibling and occurred later only when the preoccupied mother picked up the young infant. Data of this kind can lead to demonstration of a psychophysiologic com-

ponent in such a symptom and may permit a more rational approach to management.

Certain basic principles involved in the clinical examination of infants and children from this comprehensive point of view include the following:

1. Health is more than the absence of disease, and a dynamic approach is as essential to its assessment as it is to the investigation of disease.

2. Clinical study is based upon a holistic concept of the functioning of the human organism; physiology and behavior cannot be placed in separate compartments.

3. The etiology of disease involves multiple factors; whether the disorder is predominantly somatic or psychologic, predisposing, contributory, precipitating and perpetuating forces are involved. For the full understanding of any clinical condition the study must include genic, constitutional, physiologic, psychologic and interpersonal factors.

4. The family is the ultimate unit of clinical study and must be considered from the epidemiologic standpoint for both infectious and psychologic disturbances. The child cannot be studied in a vacuum.

Since the parent cannot assess accurately the technical competence of the physician, it is his manner which most effectively permits the development of confidence in him. Such a feeling *may* exist whether medication or other treatment is provided. Some parents unconsciously endow the physician with almost magical attributes, and others have unhealthy patterns of dependence which prohibit them from taking simple and obvious steps without consulting him. Among the negative parental attitudes are fear of criticism, distrust or suspicion, fear of domination or resentment toward authoritative figures. Such parents may be unable to utilize

effectively the services of the physician. Most parents, however, are able with judicious help to establish an effective relationship with the physician who is caring for their child.

The attitudes of children toward the physician are modified by those of their parents and by their own experiences. Most emotionally healthy children are able to overcome their inevitable anxieties and to develop trust in the physician. The child who is acutely ill may regress emotionally, however, and behave like a much younger child even with a physician whom he knows. Fears of pain or of the unknown and fears of going to the hospital and of being separated from the parents play an important part at such times.

The wise and experienced physician who works with children develops a capacity to view the behavior of the parent and the child as data regarding their personalities and their interaction, data which can be added to his clinical findings and may be of importance in the approach to management. In addition to sympathy and understanding, he intuitively has the capacity to put himself in their places and to sense their perspectives. With such an approach he is less likely to interpret a depressed parent's apathetic response as unconcern about the condition of the child or less inclined to label parents "uncooperative," "unreliable" or "rejecting" on the basis of first impressions.

## HISTORY

The leads which arise in securing the history during the initial interview will determine in part the points of emphasis in the physical examination and the selection of laboratory studies. Of equal importance is the opportunity for the physician to begin the establishment of an effective relationship with parent and child. The quality of this relationship will influence both the accuracy of the data obtained and the response to therapeutic measures or to anticipatory guidance. Thus the initial interview helps to establish the psychotherapeutic role of the physician. In later interviews the physician enlarges and at times revises his initial impression. It should be recognized that different physicians will apply the principles of the interview in individual ways. The physician should feel comfortable with *his* interviewing technique rather than attempt to imitate too closely that of someone else.

The following outline of information to be sought in the pediatric history is modified

from the traditional format and is intended only as a guide. Lists of this kind, however necessary, tend to promote in the student a check-list approach in history taking, which may seriously inhibit the parent's spontaneous and more detailed remarks.

The tendency to record the family or social history as "noncontributory" is a pernicious one, arising in part from the check-list practice. The details of the family's living circumstances, their position as members of a particular minority group, the chronic depression of the father over unsatisfying work experiences, the part-time work of a mother coming just at the child's bedtime, and other similar factors may be as relevant to assessment of the child's health status as factors relating directly to a physical illness. In all instances it is important to determine whether there is or has been familial illness which may be relevant to the child's illness. The experienced physician will avoid, however the monotonous listing of all possible illnesses, a feature which frequently confuses parents and may arouse resentment or self-blame in them. Rather he will inquire about symptoms causing illness or death.

In securing details of the child's birth, growth and development, past illnesses and parental child-rearing practices, it must be remembered that the average parent has difficulty in recalling such items with accuracy. Subsequent recollections or other sources of data, such as "baby books," may serve to amplify the initial recollections or to correct them. Complete blocks initially to memory of feeding, toilet-training or other similar experiences may indicate that particular difficulty or conflict was encountered at such times, and subsequently acquired data may establish the nature of it. For these reasons the physician should not place undue reliance on such data secured in the first interview.

Obviously, not all the potential information listed below can be obtained in the initial interview. In recording the history it is important to list pertinent negative items, in order to indicate that all possible aspects of the problem have been considered.

*Identification of Informant:* Initial description of parent or informant (if not parent, state relationship to patient), manner of giving data, and apparent accuracy. Evaluation of emotional state of other factors which might bear on accuracy of data.

*Chief Complaint or Complaints:* In terms of parent or child.

*Present Illness:* Date of onset and initial symptoms.

toms. Careful description of kind, duration and degree of symptoms. Chronologic progress or change in symptomatology, including details of any therapy. Correlation with significant life events. Health prior to onset. Pertinent epidemiologic information (exposure to illness, potential carriers, animal or insect vectors). Effect of illness on behavior or adjustment of patient and family. Pertinent negative data.

#### *Past History:*

#### 1. *Developmental Survey*

*Prenatal:* Health, nutrition, attitudes and emotional state of mother during pregnancy. Illnesses during pregnancy, toxemia, diabetes, cardiac disease, depression. Health and attitudes of father during pregnancy. Living circumstances of family during pregnancy. Fetal activity.

*Birth:* Date; weight; premature or term; birth order. Nature of birth; presentation; use of forceps; cesarean section; length of delivery; degree of difficulty.

*Neonatal Condition:* Spontaneous respiration; difficulty in resuscitation; respiratory distress; degree of activity; jaundice; cyanosis; convulsions; paralysis; hemorrhage; stupor; difficulty in sucking; rash; sniffles; congenital anomalies; intractable crying. Mother's condition; reaction to baby.

#### *Feeding:*

*Infancy:* Breast- or bottle fed; if artificial feeding, when started, type, frequency, amount taken; hunger. Relationship of feeding to stools; infant's response to feeding; paroxysmal fussing; sleep; vomiting; regurgitation; mother's feelings about feeding of infant; attitudes and degree of help by father.

*Supplementary Vitamins:* Age when begun; regularity of administration; amount taken; duration.

*Solid Foods:* Time of starting various items; infant's response; rashes; feeding difficulties if present, nature, time of onset.

*Weaning:* Breast to bottle or breast or bottle to cup; reason weaned; time started; length of time required; infant's response, negative reactions if present; mother's attitudes.

*Childhood:* Child's appetite; food likes or dislikes; feeding difficulties if present, nature, struggles over feeding, parents' attitudes toward food and feeding.

*Discipline:* Parents' methods; child's acceptance; negativism; tantrums; rebelliousness; aggressive or destructive behavior.

*Habitual Reactions:* Age of occurrence, degree, duration of nail-biting, thumb-sucking, rocking, head-banging, pica, rituals, others.

*School Adjustment:* Preschool experience; age of entrance into school; adjustment; attitudes and reactions of child and parents toward separation; child's adjustment (school phobia, withdrawal, aggressive behavior, day-dreaming); child's and parents' attitude toward school program; achievement or intelligence tests; child's progress.

*Social Adjustment:* Early response to separation from mother; child's relationship to peers; degree of independence; adjustment in group situations; degree and nature of participation in scouting and other group activities; difficulties in adjustment (aggressive, withdrawn, oversubmissive) if present; attitudes of child and parents.

#### *Growth and Development:*

*Psychomotor:* Age of control of head; hand-to-mouth coordination; social response; sitting, with support and alone; creeping; differentiation between parents and strangers; standing; walking, with support and alone; speech, babbling, first words, brief sentences, complicated expressions; disturbances in growth patterns, delay, regression; difficulties in coordination; speech disturbance, hesitation, stammering, infantile speech, aphasia.

*Weight and Height:* Approximate weights at one year, two years, five years, ten years; steadiness of gain; growth spurts; disturbances if present, obesity, weight loss, growth lag; reactions of child and parents.

*Sleeping Patterns:* Amount of sleep in relation to age; nightmares; disturbances in sleep rhythm; attitudes of child and parents.

*Toilet Training:* Bowel and bladder; time begun; methods used; age control achieved; difficulties if present; later relapses in control, enuresis or encopresis; parents' attitudes.

*Sexual Development:* Child's questions regarding conception, pregnancy, or differences between boys and girls, information given; preparation for menarche, age of onset, secondary sex characteristics, girl's reaction; preparation of boy for puberty, age of onset, secondary sex characteristics, boy's reaction; parents' attitudes and feelings; attitudes toward nature of relationship with opposite sex; acceptance of male or female role; occurrence of masturbation; difficulties in sexual adjustment if present, attitudes of child and parents.

#### 2. *Medical Survey*

*Prophylaxis:* Immunizations against smallpox, pertussis, diphtheria, tetanus, poliomyelitis, scarlet fever, typhoid fever, Rocky Mountain spotted fever, yellow fever; age at immunization, number of injections, booster shots, untoward reactions; evidence of artificially induced immunity, scar of smallpox vaccination, Dick and Schick reactions, if done; tuberculin and serologic tests for syphilis.

#### *Specific Illnesses:*

*Contagious Diseases:* Measles, rubella, exanthem subitum, pertussis, chickenpox, smallpox, scarlet fever, diphtheria, mumps, poliomyelitis, others; age at illness, degree of severity, complications.

*Other Illnesses:* Listed according to system involved; age, severity, treatment, sequelae; reactions of child and parents to treatment, hospitalization, or to any continuing disability or treatment; reaction to serum, blood or blood derivatives, chemotherapeutic or

antibiotic agents, if administered.

*Allergic Reactions:* Eczema, asthma, hay fever, urticaria, hypersensitivity reactions to inhalants, food, drugs, contact with cloth, soaps, and so on.

*Operations:* Dates, nature, results; complications or sequelae; reactions of child and parents.

*Injuries:* Dates, nature and circumstances of accidents, sequelae; nature of study and treatment; reactions of child and parents.

### Review of Systems

*Head:* Headache, trauma.

*Eyes:* Vision, glasses, strabismus, pain, inflammation, diplopia, other disturbances.

*Ears:* Hearing, pain, discharge, tinnitus.

*Nose:* Discharge, epistaxis, obstruction, disturbances in olfactory sense.

*Teeth:* Extractions, disorders in dentition, abscesses, general condition.

*Mouth:* Mouth-breathing, sore mouth, sore tongue, caries, bleeding gums, taste.

*Throat:* Pain, infections, tonsillitis, difficulty in swallowing, hoarseness.

*Neck:* Masses, pain, stiffness, cervical adenitis, thyroid enlargement.

*Respiratory:* Frequency and nature of colds, cough, sputum, hemoptysis, stridor, foreign bodies, croup, bronchitis, asthma.

*Gastrointestinal:* Appetite, food idiosyncrasies, vomiting, abdominal discomfort or pain, constipation, diarrhea, encopresis, character of stools, jaundice.

*Cardiovascular:* Dyspnea, cyanosis, edema, precordial pain, palpitation, syncope.

*Genitourinary:* Enuresis (diurnal or nocturnal), frequency, urgency, dysuria, circumcision, vaginal discharge, menstrual disturbances.

*Musculoskeletal:* Weakness, joint or muscular pain or swelling, posture, muscular coordination, deformities, fractures.

*Nervous:* Sleep disturbances, tics, tremors, vertigo, twitchings, convulsions, ataxia, paralysis, projectile vomiting, shortened attention span, distractibility.

*Skin:* Eruptions, congenital anomalies, itching, pigmentation, erythema, blushing, bruising, petechiae.

### 3. Family Survey

*Parents:* Age; occupation; state of physical and emotional health of each parent or parent substitutes, currently and at important points in patient's illness; if parents not living, age at death, cause, and nature of symptoms; adequacy of marital relationship; individual attitudes of parents toward patient and toward child-rearing practices; previous pregnancies of mother, outcome, nature of abnormality; brief summary of family circumstances; socio-cultural and ethnic backgrounds from which each parent derived; current state of health of grandparents (if not living, age at death, cause, nature of symptoms, age of patient at time of grandparents' deaths).

*Siblings:* Age; where living; state of health (if not living, age at death, cause, nature of symptoms, age of patient at time of death); general

school and social performance; nature of relationship to patient; attitudes of parents toward patient in relation to siblings.

*Living Circumstances:* Place; nature of dwelling; nature of sleeping arrangements; number of persons living in home in addition to parents and children; nature of relationships of such persons to family members; members of family who work; working hours if unusual; general level of economic independence, support from community agencies if any; neighborhood circumstances; available recreational outlets.

*Familial Illnesses or Anomalies:* Tuberculosis, syphilis, diabetes, cancer, epilepsy, rheumatic fever, allergy, hereditary blood dyscrasias (including Rh status if known), mental illness, mental retardation, dystrophies, congenital anomalies, heredo-degenerative diseases.

*Summary:* A brief recapitulation of the essential features of the present illness or the current state of health if the child is being seen for a health examination; significant correlations between features of past development or illness and significant life events or family circumstances; essentially an organization and synthesis of the historical data into meaningful trends, so far as they can be seen up to this point.

The recorded history of the experienced physician may more closely approximate an expanded summary rather than the basic outline suggested, but for the person in training an outlined plan is essential. With the use of the general approach indicated it is possible to secure psychologic and social data at the same time as somatic factors are explored.

The most valuable aid to the establishment of a positive relationship with the parent and to the attainment of accurate historical data is the manner of the physician, who communicates nonverbally his interest and confidence in the parent through his facial expression, tone of voice, and posture. An unhurried, accepting, respectful and noncritical mien, even if time is limited, is most important, and privacy is essential.

Young children of preschool age are usually seen with the mother. The physician may wisely give the child a toy, appropriate to his age level from a varied supply available in his office, or may offer him a throat stick or other object with which to play. Such an approach indicates to the parent the physician's interest in the child and provides a beginning positive contact with the child. If the parent's concern is the child's behavior, or if the parent talks too freely about the child's personality, the physician may prefer, with the help of a nurse or secretary, to interest the child in some play activity in the waiting room while he talks with the parent.

With older children and young adolescents it is best to see the parent and child together at the first interview, since an anxious or suspicious child may fear that the parent is imparting secret information to the doctor. If it is necessary to see the parent alone for free discussion of emotional problems, this may be done at a later separate interview. Occasionally, if the parent wishes to discuss some urgently disturbing aspect of the child's behavior, the initial interview may be without the knowledge of the child; at this time it can be decided whether the child should be seen alone or with the parent. Whenever both parents can be seen together, with or without the child, valuable impressions may be obtained regarding their relationship, their attitudes as parents and their attitudes toward the child and his illness or adjustment.

If the child is acutely ill, the physician should take only a brief history relative to the current illness before beginning the physical examination. Subsequently the history should be completed.

**Interview with the Parent.** At the outset it is important to permit the parent to talk freely without significant interruption about the problem which concerns her most. Leading questions must be avoided. Even if the physician's time is limited and the parent's initial comments seem confused, too detailed, or irrelevant to the child's obvious condition, the parent should be allowed to talk freely and to set the pace, for at least a brief time. Such a practice permits the parent to talk about the main source of concern and helps to strengthen her impression that the physician values her observations. In addition, the act of talking helps to discharge initial tensions and thus to assist her in overcoming anxiety or fear about the doctor's findings or opinion. Experienced pediatricians have found that a few extra minutes during the initial interview will save time later. With such an approach it may become apparent that the declared reason for a visit or the stated "chief complaint" may not be the source of the parent's concern. For example, the mother of a mildly obese boy of nine, who seeks guidance about his weight, may indicate with some embarrassment in the course of such a relaxed interview that her real concern is the apparent small size of his genitals.

As the interview proceeds the physician may ask pertinent questions about particular details of importance or to round out areas of information left untouched. Rather than rapid-fire questions which permit only a

mechanical "Yes" or "No" answer and preclude any initiative on the parent's part, the physician can use general questions such as, "Can you tell me a little more about his difficulty in breathing?", or, "How about toilet training?" At times he may simply repeat a key word or phrase, indicating by his inflection encouragement for the parent to elaborate. An approach of this kind will permit the parent to bring out many important facts which might otherwise be forgotten or pushed aside as insignificant. In a health examination the parent may thus bring up pertinent data or urgent questions about feeding, weaning, toilet training, the handling of discipline, accident prevention and other vital topics. Some parents may react with oversensitivity or suspicion if the physician focuses too closely on their own behavior or background, at least in the initial contact, before a trustful and secure relationship has developed.

Certain historic data may carry an emotional charge for the parent, and revelations of fact may be painful and difficult. This is particularly true of the history of familial illnesses and emotional disturbances in child or parent. For example, some parents of children with seizures may be unable to disclose during the initial interview the presence of epilepsy in close relatives, because of their fear that they have been personally guilty of transmitting the illness. Parents also recognize that their feelings about the child may be involved in disturbances of his behavior. Thus in following up leads to possible psychologic problems or in asking questions dealing with areas of behavior, it is important not to adopt too frontal an approach, which the anxious parent may misinterpret as a critical attack. Questions such as, "Did you want this child?", "Does your son masturbate?", or "Was she jealous of the new baby?" are all too frequently doomed, in the initial interview, to receive conventional and socially acceptable replies or to be answered with defensive indignation. Such information is important, but must be gathered initially by inference or by the use of less loaded and indirect questions, such as, "Were you able to plan the pregnancy for this child?" or, "How did she seem to take the new baby's arrival?" Later, when a positive relationship has been established with the parent, more detailed and accurate information of this kind may be obtained.

At times parents may become silent or may fail to answer a question, especially if it carries emotionally charged implications. At such points it is wisest for the physician to hesitate

for a moment or two. Much highly significant verbal or behavioral data may emerge under such circumstances, which would only be inhibited by premature shifting of the topic or by too rapid reassurance. The observation of nonverbal behavioral data, such as blushing, nail-biting or neuromuscular tension, may give important clues to be followed later. The practice of expectant waiting is vital even if the mother appears on the verge of tears. The physician can, with practice, curb his natural social impulse to stem the expression of strong emotion, such as an outburst of crying by a tense and troubled mother. The release of such feeling in a sympathetic atmosphere may be of real help to the parent and may strengthen the relationship with the physician. The physician may indicate simply that he understands and avoid any immediate attempts to assuage such seemingly illogical feelings.

In closing the initial interview it is wise to return to the area of the parent's major concern, which may not always be the initial complaint. Such a step provides an opportunity for the physician to ask questions arising from the leads which he has gained up to this point. This technique also gives a kind of closure to the interview which indicates to the parent that the physician has comprehended fully her concern and will endeavor to deal constructively with it during further studies.

**Interview with the Child.** With a preschool child or with a child who is acutely ill the factual information gained from talking with him may be of little value. With older children, however, the data obtained can be of real importance, particularly as to how the child regards his illness, any consequent physical limitation or his state of health in general. Occasionally only the child has the pertinent information, as concerning some toxic substance accidentally or intentionally ingested or the subjective quality and the location of pain or discomfort. While interviewing the parent it is possible to interject questions to the older child, thus making him feel that he is involved in the solution of the problem.

With the preschool child one may learn a good deal in a few moments of casual observation of his play during the interview with the parent, especially if toys are provided. One may obtain impressions of the level of his development from the degree of complexity and organization of his play, the length of his

span of concentration, his drawing, and other factors. His attitude toward the physician, often reflecting parental anxiety, may also be apparent in his drawings, his play with dolls or his general demeanor.

With the older child, interviewed separately or with the parent, verbal data may be much more accurate and voluminous after a positive relationship has been established. In the first contact, school-age children may be inhibited and withdrawn in the face of anxiety without any deep underlying emotional disturbance or limitation in intellectual capacity. The wise physician will avoid premature judgment as to the child's capacity for adjustment. With the child who is old enough to talk freely one can and should gain impressions, even in predominantly somatic illness, of the meaning to him of his symptoms or disability, in terms of its effect upon his adjustment at school, his status with his peer group, and other factors. With frightened or withdrawn children, data of this sort may have to be sought indirectly by asking them for their aspirations, what they wish for most, what they would do if they were well, or even what a hypothetical child might wish for or do in a particular situation.

In early contacts with children, whatever the problem may be, it is wise to avoid questions of anxiety-provoking potential, such as those about sex activity and hostile feelings. The child is not accustomed to discuss such matters comfortably with adults and may become more inhibited or deny any such activity or feelings. Later he may be able to unburden himself to the physician, finding this more neutral but understanding relationship a safe one in which to discuss topics which he may have difficulty in bringing up with his parents.

**Observation of Child and Parent.** The importance of careful inspection of the child and of detailed observation of the parent-child interaction is unfortunately frequently overlooked. Such rich clinical impressions are available to the physician from the moment the parent and child enter his office and indeed may be obtained by him or by an alert nurse or secretary even during glancing observations in the waiting room. For example, pallor, dyspnea, extreme inactivity or listlessness, significant overactivity and short attention span may easily be recognized. Disturbances in gait, limitations in the use of a limb or the degree of exercise tolerance permitted by a congenital cardiac anomaly will

often be much more accurately assessed during casual observation of the small child's play than during the formal examination.

In addition to such clinical data, the physician may obtain important impressions regarding the interaction of child and parent. The school-age child who clings anxiously to the parent and the parent who appears over-protective for the child are readily apparent. Some parents cannot permit the child to answer a question independently, manifesting the need to dominate the child or the situation. Other parents may constantly correct the child or require him to sit impossibly still, indicating unrealistically high standards of conformity. If the father and mother are interviewed together, they may disclose disagreements in child-rearing practices. A few parents pay too little attention to their children, such as the mother who does not stand close to her infant to prevent his falling off the examining table. Occasionally, disturbed parents unconsciously may need to deny the extent or seriousness of the child's obvious illness and to belittle him or to urge him to act "as if he were well." Even balanced and effective parents may exhibit some of these behaviors at times of anxiety. The wise physician will note such impressions and test them against later observations. Such data may later be vitally important in approaching the management of a negativistic diabetic child, for example, or in understanding the sources of overdependent behavior. Observational data of this sort are more readily available to the physician who visits the family's home and enjoys continuity of contact with the parents and child over a long period of time. On a home visit the standards of parental care and the pattern of family living are much more obvious.

## PHYSICAL EXAMINATION OF THE CHILD

In this section certain basic principles involved in the direct study of the child will be presented; no attempt will be made to discuss in detail the techniques of physical examination. Some thought should be given to the appearance and arrangements in the office or the examination room. Most pediatricians recognize that children respond to bright colors. It is further known that white is a cold and strange color to the small child; pastel colors achieve a cheerful and familiar effect. The room should contain some pictures and other colorful items.

**Approach to the Child.** The physician will

have gained certain impressions during the taking of the history of the child's general physical and emotional state, and the nature of any illness, as well as of the interaction between child and parent. With this background he may turn to the child at an appropriate point. He can anticipate active participation in the examination by the child, but he should be prepared for resigned submission, passive resistance or, more rarely, active refusal or violent battle. The degree of rapport established with the child and the parent may determine the diagnostic success of the examination. Subtle changes in cardiac or chest sounds, for example, cannot be detected effectively by auscultation in the loudly crying, squirming child, nor can ocular fundi or deep tendon reflexes be accurately appraised. It is necessary at times to examine acutely ill children during states of crying or resistance; at such times there is no substitute for experience, skill and clinical judgment. In the seriously ill child the physical examination may be combined with the latter portion of the history to save time and to decrease the suspense of the anxious child and the parent.

The child should ordinarily be undressed by the mother or nurse prior to the examination. All clothing should be removed from young children. It is well to remember that refusal by preschool children to remove certain items of clothing may indicate anxiety over being so completely exposed rather than sexual modesty. This initial apprehension should be respected; it is ordinarily soon overcome. Older children may retain their underpants, with temporary dropping for genital examination when the child is at ease.

No matter what the circumstances, the physician must at all costs preserve a relaxed and unhurried approach. A few moments spent initially in conversation with the child about a doll or in admiring an item of clothing, using the child's first name or nickname, may save valuable time and considerable struggle. However, the physician must avoid being overlong in the initial preparation. Tension in both child and parent may build up if the examination is postponed too long, no matter how well-meaning the physician may be in his preparatory efforts. Some explanation of each step, as in examining the throat or darkening the room for ophthalmologic examination, can be given in a quiet and soothing voice, using terms the child can grasp. Although it is important for the physician to be able to relate to the child, he

should not lower himself to the level of the child; he must remain an adult in the child's eyes. It is axiomatic that the child be told the truth at his level of understanding whenever uncomfortable procedures are to be performed; any other course will detract seriously from his later trust or cooperation.

The young child may be permitted to explore certain instruments such as the stethoscope before they are used; attempts at listening to themselves or their dolls may be enjoyed and may overcome tension. "Blowing out" the light of the otoscope is a time-honored pediatric detractor for the toddler.

*Special types of handling are required for infants and children at their different levels of development.*

With the very young infant little difficulty may be encountered if the mother is relaxed and trusting. Pacifiers may be used to diminish crying or restlessness. If feeding time is imminent, much of the examination may be carried out while the mother holds and feeds the infant. An excellent opportunity is thus afforded for the young mother to bring out questions or fears about the infant's body or stage of development.

In the latter part of the first year most infants show some fear of the physician, even if they have seen him regularly for health examinations. This change represents the developing capacity of the infant to distinguish strangers from the mother and his growing awareness of himself as an individual who may be separated from the familiar parent. This phase may persist well into the second year. At this stage it is wise to avoid sudden moves or loud vocal tones in the direction of the infant. The physician may offer the mother a throat stick or similar object to give to the infant while he sits in her lap during the interview, permitting him to appraise the physician from a safe vantage point. If he is crawling or toddling, the infant may later move toward the physician during the history and make overtures himself, thus effecting a more successful relationship than if he is approached.

At this age infants often resist examination on their backs on an examining table, and it is best to examine them on the mother's lap, permitting her to hold his head against her shoulder for examination of the ears and throat. Often the nurse may be able to obtain a more positive initial response from the older infant than the less familiar male physician with a deeper voice. Anxiety or even terror

initially by the infant need not be considered by the physician a sign of failure.

During the latter part of the second and most of the third year the child often exhibits so-called normal negativism, reflecting a healthy drive toward independence and aggressive self-assertion. Asking a child of this age to perform a particular step in the examination, such as opening the mouth, almost invariably results in a firm "No." Patience is of the essence. A stubbornly negativistic child may, if interested in some other activity, later become suddenly able to overcome his previous rebellious stand. Battles almost inevitably result in loss of trust in the physician.

The preschool child can ordinarily be examined on the table. Most children at this stage, however, are frightened when they have to lie down, and they feel less anxious in a sitting position. Each move should be explained briefly, with time permitted for spontaneous questions.

With children of school age, as with older preschool children, much can be learned during the physical examination about the child's attitudes toward his own development, his feelings about himself or herself as a developing boy or girl, and his concern over minor blemishes or abnormalities. If the child feels secure with the physician, he may himself bring up his fears or misconceptions. At times the parent also will bring up similar concerns during an unhurried examination.

With preadolescents and adolescents modesty may become an important feature in the examination. Respect for such feelings should prevail, and children at this stage should be handled in relatively the same way as adults. Adolescent boys may entertain fears about a growth lag bearing upon their ultimate masculinity, or they may have concerns about other deviations from the normal. Adolescent girls may exhibit parallel concerns, particularly around the onset of the menses and the development of secondary sex characteristics. A nurse should be in the room during the examination of girls of this age.

**Approach to the Parent.** Some busy and impatient physicians prefer to exclude anxious mothers from the physical examination, recognizing that the child often submits more passively in her absence. This approach carries with it not only the pain of separation for the young child, particularly acute for the overdependent and frightened child of an overanxious mother, but also the implication for the child of punishment by the physician.

The parent, too, may react with feelings of guilt and at times resentment because of her fear that the physician believes she is a poor parent. It is almost always wisest to permit the parent to remain with the infant or young child.

At times a particularly apprehensive parent will ask to leave during the physical examination and should ordinarily be permitted to do so, preferably before rather than during the examination. Occasionally an extremely difficult situation arises in which the child clings dependently to the mother or father, who is too anxious or too helpless to assist the child in going through with the examination. If patience and preparation of the child fail and he is not acutely ill, the examination can often be held to absolute essentials on the first visit, with postponement of other details and routine laboratory procedures to a later visit. If the child is acutely ill and must be examined thoroughly, it can be suggested to the parent without criticism that the examination may be upsetting to her and that she may prefer to wait outside, the nurse taking her place. Some parents can remain and relax in such situations if the responsibility for gentle but firm restraint of the young child is taken over by the nurse.

If the mother leaves the room, it is wise to tell the child where she will be and when she will return. If restraint is indicated under such circumstances, it should be carried out promptly after a brief explanation of its need.

**Method of Examination.** In examining children it is important that instruments applied to the skin, such as the stethoscope, be warm. It may be of help, with a young or anxious child, to rinse the hands in warm water before beginning the examination, since any coldness to the touch may add to the child's fear or resistance.

The usual order of procedure in the examination of adults is not appropriate for young children. In general, it is wiser to begin with a peripheral and neutral step, leaving the more sensitive head and associated structures until later, in order not to frighten or arouse resistance. This approach may vary with the age of the infant or young child as well as with circumstances surrounding the examination. For the older infant deep tendon reflexes may be a suitable point of departure. Some physicians may find it more effective to use the stethoscope, first playfully on the legs, then abdomen, and finally chest. With the preschool child listening to the chest may be the appropriate opening move. An occa-

sional child is made more anxious by waiting too long for the anticipated and disliked throat examination, and in such instances it may be wiser to perform this earlier. When restraint is required, the need for it should be explained, and then the examination should be made with as much dispatch as is commensurate with gentleness and thoroughness.

Pulse and respiratory rates and blood pressure levels in infants and young children are variable and may be altered by fear or apprehension. Only persistent deviations can thus be relied upon. In young children, in particular, temperature may also be influenced by emotions or activity. Rectal temperatures may be elevated as much as a degree Fahrenheit immediately after active exercise, whereas the oral temperature usually is not. Oral temperatures may be altered immediately after ingestion of hot or cold substances. Rectal temperature recordings are generally considered to be nearly a degree higher than oral ones, but there is a lesser difference if each recording is made appropriately. Rectal temperatures are preferable in infants and small children. Preschool children may resist this approach, although not yet able to retain the thermometer safely by mouth. In such a situation an axillary or groin reading will give an approximate figure, at least a degree lower than an oral reading, which may suffice for the moment.

Examination of the heart and lungs is complicated in infants and young children by the thinness of the chest wall and the consequent relative loudness of breath sounds. Sounds resembling bronchial breathing are frequently heard over the right upper lobe in normal chests. The physician must learn to listen quickly and accurately during periods of freedom from crying or other vocal activity. Many young children cannot cooperate easily on tests for tactile fremitus or vocal resonance. Advantage must be taken of spoken words, the use of a "blowing" game or even periods of crying.

In examining the abdomen of a child considerable time must be spent in putting the child at ease in order to achieve sufficient relaxation of the abdominal musculature. Talking with the child is often helpful in diverting his attention. If the child is old enough to respond to a request to take a deep breath, the pressure of the physician's hand can be increased gently with each inspiration without undue voluntary resistance.

For children beyond early infancy rectal examinations may be disturbing and need not

ordinarily be included as a part of the health examination. Inspection of rectal and genital areas can be done routinely, and a rectal examination carried out if indicated. Caution should be observed in this procedure or in vaginal inspection with preadolescent or adolescent girls, since their apprehension and misconceptions about such manipulations may be extreme.

After the examination the child should be given time to ask questions, if he desires, about procedures or instruments used or about any other phase of the examination. The physician should always terminate the interview with a friendly and personal farewell to the child.

### LABORATORY DIAGNOSTIC STUDIES

The indications for specific laboratory or other diagnostic tests are discussed in the sections on specific diseases. Routine procedures in the course of any clinical examination should include hemoglobin, white blood cell count and differential, urinalysis and a tuberculin test. Routine serologic studies for syphilis have been discontinued in some pediatric clinics.

When additional laboratory studies are contemplated, they should be critically selected on the basis of their relevance to the problem at hand. Many physicians recognize that it is best to disturb the seriously ill patient as little as possible by venipuncture or other tests which involve vigorous moving of the patient or the possibility of the arousal of anxiety. Tests vitally necessary to the diagnosis and determination of the course of treatment should of course be done. Nevertheless patients in cardiac failure, for example, can be detrimentally affected by a battery of tests as a result of the effects of fatigue and anxiety upon the cardiorespiratory system. Possible secondary effects, such as subdural effusion arising from use of the pneumoencephalogram, should also be considered. Internal and external jugular punctures have fortunately been largely abandoned in infants in favor of femoral punctures or other less potentially physically traumatic procedures in securing blood. The need for interpreting carefully the indications for laboratory tests to anxious parents is fundamental in any diagnostic approach.

When painful procedures such as throat cultures, venipunctures, blood cell counts, intradermal tests, as well as more involved procedures, are to be performed, it is essential

that the child be told briefly what will happen in terms he can understand. He can be told that a finger prick or venipuncture is necessary in order to choose the right medicine to "help his throat stop hurting" or some such simple and concrete explanation. The child should be given enough time to ask questions in advance of the procedure. Sufficient explanation should be given to the parent also, even about brief and simple procedures. If restraint is indicated, the child should be told that his arm or other body part will be held in order to help him hold still so that the procedure will be less painful. Many well adjusted parents cannot hold children for painful procedures involving the sight of blood, and the nurse may do this more effectively, the parent remaining in the room if possible. Too long a period of anxious questioning and delay may permit the build-up of excessive anxiety.

After the procedure many younger children and even those of school age cry briefly. The child should not be made to feel that he should not cry or that it is "bad" to do so. If parents express this attitude, as many do, because of fear of criticism by the physician, it is wise to indicate that it is difficult for the child not to cry. In addition, the recognition of the fact that the doctor is not angry or critical is important to the child and the parent. In certain instances the physician may let the child know also that he realizes that the child may be angry momentarily with him for the use of a needle, thus helping the child to avoid the necessity for complete suppression of negative feelings.

Major diagnostic or therapeutic procedures, such as thoracentesis, paracentesis and cardiac catheterization, must of course be carried out in the hospital, and the child should be prepared for admission to the hospital as well as for the procedure itself. Although hospitalization need not be an emotionally traumatic experience, the chances of such an eventuality are great enough that the psychologic aspects of admission and management should not be overlooked. For the child under four years of age, and for some older but dependent or definitely disturbed children, the concomitant separation from the mother, often misinterpreted as punishment, is the most anxiety-provoking aspect of the experience.

With the young preschool child verbal preparation may be of limited value, but should nevertheless be undertaken. Preparation should be discussed by the physician with

the parents, who may have questions, often seemingly irrelevant ones, which may reflect their own apprehensions or a tendency toward self-blame in relation to the child's illness. A period of several days is usually sufficient for the preschool child to bring up questions, misconceptions and potential misinterpretations about the coming experience, which parents can then discuss with the child if they themselves have a reasonably clear grasp of the facts involved. Actual explanation to the young child should be couched in simple terms, related to the need for "getting well" or helping the child's "tummy" to stop hurting. Concrete facets of the experience are best explained, such as the dress of doctors and nurses, the procedures involved in admission, hospital sleeping arrangements, the experience of anesthesia, and the use of bed-pans. A nurse or social worker can be helpful in discussing such factors with the parents prior to elective hospitalization.

The older child can be prepared further in advance in accord with his greater capacities for intellectual understanding and his ability to tolerate, for longer periods of time than the preschool child, the tension involved in the anticipated hospitalization. For preschool and school-age children the opportunity to "play out" feelings of fear or resentment is important, both before and after the hospitalization or painful procedures. Opportunity for the use of dolls, doctor kits, and Plasticine or other play materials should be available to the child for this purpose in the hospital. Occupational therapists or recreational therapy personnel can contribute significantly to such constructive and age-appropriate modes of adaptation.

Frequent parental visiting is valuable in preventing disturbed reactions to hospitalization. Overnight stay in the hospital by the mother may be a most effective support for the young or very anxious child, provided the parent feels comfortable in doing so.

Sedation may be used in preparation of the child for major diagnostic procedures, and general anesthesia with a rapidly effective and short-acting agent may be justified in certain instances. Sedation or anesthesia as aids in the management of a child under such circumstances, however, should not be substituted for psychologic preparation.

Psychologic tests, when indicated for the estimation of intellectual capacity or for the assessment of personality patterns in projective studies, should be performed by a competent psychologist. The physician must

recognize the limitations of a single intelligence quotient, especially with an ill or hospitalized child who has regressed behaviorally and may test below his actual level. Repeated tests and continued study are necessary before a diagnosis of retarded development is accepted in an infant or young child.

The need to take all possible etiologic factors into consideration in arriving at a diagnosis and plan of treatment in a given situation has been emphasized. For example, if a physician is confronted with an initial attack of acute bronchitis, his therapeutic approach is correctly based on the probability of a nonrecurring acute infectious disorder. If the bronchitis recurs several times or continues, however, he must seek further for *predisposing* and *contributory*, as well as for *precipitating*, etiologic factors. After some study it may be found that the child has a *predisposing* allergic diathesis of familial nature. *Contributory* factors may include the presence of chronically diseased adenoids, as well as chronic undernourishment as the result of a feeding problem since early infancy. *Precipitating* influences may derive from incidental upper respiratory tract infections, as well as episodes of exposure to cold weather without sufficient clothing as the result of rebellion by the child against parental overconcern. Chronic sinusitis may be a *perpetuating* factor. In arriving at the conclusion that the foregoing clinical pattern represents the so-called bronch sinusitis syndrome, the physician recognizes the contribution of psychologic or interpersonal factors in the undernourishment and the rebellion against parental overconcern.

In such a comprehensive evaluation concurrent or relevant somatic factors are put into perspective with pertinent psychologic ones. Correlations between significant life events and symptomatic exacerbations, established from the history and observational data, may provide important clues to psychophysiological influences, involving multiple etiologic forces, in many illnesses such as ulcerative colitis, asthma, peptic ulcer, hyperthyroidism. With such an approach the physician will avoid either somatic or psychologic overemphasis.

#### IMPLEMENTATION OF RESULTS OF THE CLINICAL EXAMINATION

Once the physician has achieved a balanced diagnostic appraisal of the child in his family setting, his plan of therapy or his approach

to well-child care must be communicated effectively to patient and parents. He should be confident and at times authoritative in his formulation and recommendations, but humility, patience and understanding remain paramount. In discussing the child's condition with his parents the physician will do well to remember the intense apprehension with which they often await the diagnosis and recommendations. He should repeat in simple language, without recourse to medical terminology, his suggestions for therapeutic plans and write out the detailed or complicated instructions for care. Many parents remain so anxious throughout such a final interview that they may indicate understanding at times when they are too confused to retain details or even to grasp implications. An opportunity for the parents to talk freely

about their reactions will bring out many misconceptions or misunderstandings which must be patiently dealt with if therapeutic or preventive measures are to succeed.

The role of the physician dealing with children and their parents is an exceedingly challenging and uniquely satisfying one. Parents are turning with increasing frequency to the physician for guidance. To bring a comprehensive approach to the clinical examination, the physician must have increased knowledge of human biology in its behavioral as well as its physiologic aspects. With such knowledge he is in the best possible position to foster the detection, treatment and prevention of disease and to assist in the positive promotion of healthy adaptation.

DANE G. PRUGH

## DISTURBANCES OF FLUID AND ELECTROLYTE EQUILIBRIUM

### PHYSIOLOGIC CONSIDERATIONS

Physiochemical conditions in the body are kept within narrow limits of variability by a close integration of various physiologic processes. This tendency to maintain homeostasis is exemplified by the manner in which the electrolyte equilibrium in the blood plasma is maintained in health or disease. Serving as a medium for the transport of metabolic materials within the body, the blood constitutes an internal environment for the tissues; it both affects and is affected by the metabolic activities of all the cells it bathes.

In health the quantity of circulating plasma is remarkably constant, being about 5 per cent of the body weight (slightly more in infants); the interstitial fluids comprise 15 per cent and the intracellular fluids 50 per cent of the body weight (Fig. 32). In abnormal conditions, changes in volume and composition of the blood plasma reflect closely the changes in other body fluids. The total volume of fluids in the body depends primarily on the intake and outgo of water, nutrient materials and metabolic products through the gastrointestinal tract, kidneys, skin and lungs. The water content of the different fluids is closely correlated with their content of salts and, to a less extent, of other osmotically active substances; thus movements of water and salts

into and out of the body and between the various fluid compartments of the body are closely interdependent.

In the gastrointestinal tract a constant turn-

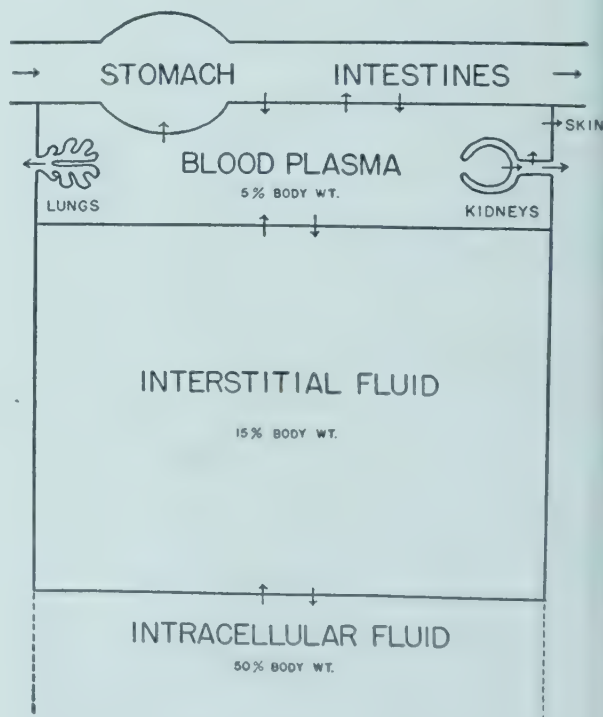

FIG. 32. Distribution of fluids in the body. (J. L. Gamble.)

ver of large quantities of fluid is involved in the secretion and reabsorption of digestive juices, which are practically isotonic with the blood plasma. Failure of reabsorption of these juices, through loss by vomiting or diarrhea, results in depletion of body water and electrolytes. The total osmolarity of the blood plasma tends to be remarkably stable even under conditions involving considerable alterations in its volume and in the concentrations of its constituents. This stability is attained largely through renal mechanisms which serve to control the total concentration of electrolytes in the plasma and to make compensatory adjustments in the concentrations of individual ions when the electrolyte equilibrium is disturbed.

The ionic equilibrium in the electrolyte system is linked with many phenomena of growth, structure and function through the influence of hydrogen ion activity (pH) on enzyme systems and through specific effects of other ions, such as the effects of changing concentrations of calcium and potassium on skeletal and heart muscle, and of carbon dioxide on the respiratory center.

**Acid-Base Relationships.** Normally, blood is kept slightly alkaline, within the narrow range of pH 7.35 to 7.45, by equilibria among a number of buffer systems. Buffers, mixtures of weakly ionized acids and their salts, tend to keep changes of pH minimal when a strongly ionized acid or base is added to their solution. The principal buffer systems of the blood are represented as

(where *B* is "base" or cation equivalents, *Hb* is hemoglobin, and *Pr* is proteins other than hemoglobin).

The ratio between the acid and salt in each buffer system at a given pH depends on the dissociation constant of the respective acid; for the carbonic acid-bicarbonate buffer, the ratio is 1:20 at pH 7.4. Hemoglobin is the most efficient of these buffers, but bicarbonate has special value for defense against increases of anions in the blood, because, when bicarbonate is decomposed by the addition of acid, the lungs liberate and excrete volatile carbon dioxide, thus leaving cations available to neutralize the added acid. Hence bicarbonate has been called the alkali reserve of the body.

Of these buffers, the carbonic acid-bicarbonate system is of most interest to the clinician, because its state is the easiest to determine by simple laboratory methods and

because its correlation with clinical conditions is generally the most apparent. For clinical purposes it is sufficient to say that the pH of the blood depends upon the ratio between the concentrations of carbonic acid and bicarbonate in the blood plasma: i.e., the normal pH value is sustained irrespective of absolute changes in the concentrations of carbonic acid and bicarbonate if the ratio 1:20 between the two concentrations is preserved. Since the concentration of carbonic acid depends upon the rate of formation of carbon dioxide in the body and of its removal from the blood by the lungs, the immediate defense of this ratio is primarily a function of the respiratory mechanism. The concentration of bicarbonate, dependent on the balance between the total cations and the anions other than  $\text{HCO}_3^-$ , is governed by mechanisms of absorption and secretion in the gastrointestinal tract and kidneys that determine the general electrolyte structure of the plasma.

The kidneys control the electrolyte structure of the body fluids by their ability to secrete urine of varying concentration and acidity or alkalinity according to the need for excretion of excess anions or cations. The pH of urine normally is around 6.0, but may vary within the wide range of 4.6 to 8.0. The pH of acid urines is determined mainly by the ratio of acid to alkaline phosphates; the pH of alkaline urines is determined mainly by the ratio of carbonic acid to bicarbonate.

Metabolic activities result in the production of large amounts of acids that require disposal, such as carbonic, lactic, pyruvic, beta-hydroxybutyric, acetoacetic, phosphoric, sulfuric and hydrochloric. In the absence of disease, acid metabolites are transported from their site of formation to their point of disposal with minimal disturbance of the tissues and with minimal alteration in the blood by the buffer systems.

Carbonic acid ( $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{CO}_3$ ) is the most abundant metabolic product of the body. Though most of the carbon dioxide in the blood is in the form of bicarbonate, that carried by hemoglobin accounts for about 90 per cent of the total turnover of carbon dioxide taken up in the tissues and liberated in the lungs. Rapid release of carbon dioxide in the lungs is mediated by the enzyme carbonic anhydrase in the red blood cells. Phosphoric, sulfuric and hydrochloric anions are excreted mainly in the urine.

Some organic acids, when produced in moderate amounts, may be metabolized by

FIG. 33. Acid-base composition of blood plasma. (J. L. Gamble.)

certain tissues, i.e., reutilized to some extent or burned to carbon dioxide and water, but excessive amounts in pathologic conditions must be excreted. The excretion of different anions entails losses of mineral cations from the body according to the kind and amounts of the acids excreted; such losses are kept minimal chiefly by excretion of the anions in the form of ammonium salts and acid phosphates. In extremely acid urines part of the organic acids may be excreted in the free state. On the other hand, in conditions of alkalosis the excretion of bicarbonate by the kidneys serves to conserve mineral anions (as Cl<sup>-</sup>) in the body.

**Cation-Anion Balance.** The "ionogram" in Figure 33 represents the principal components of the plasma electrolyte system in terms of milliequivalents per liter. The expression of the concentrations of the electrolytes in terms of chemical equivalents has great practical value, since the summation of separately determined cations and anions permits ready visualization of the total ionic equilibrium (commonly called acid-base balance) and of adjustments in the electrolyte structure that occur in pathologic conditions.

The electrolyte structure of interstitial fluid is similar to that of plasma except for a low protein content, a slightly lower concentration of total base and a somewhat higher concentration of chloride.

In the soft tissues of the body (intracellular fluid) potassium and magnesium comprise most of the cations, while proteins and organic phosphates comprise most of the anions. Intracellular chemical changes are probably more closely related to functional disturbances than are the better known ones in the extracellular fluids. Changes in the latter provide evidence of factors that affect both the structure and function of the cells by influencing ionic exchanges between them and extracellular fluids.

Two examples serve to emphasize this point: (1) Acidosis has inhibiting effects on several phases of carbohydrate metabolism. Lowered pH of the blood appears to inhibit the action of insulin by interfering with processes of phosphorylation involved in the concomitant cellular uptake (normally stimulated by insulin) of sugar, potassium and phosphorus from the blood plasma. (2) The direction and speed of transfer of potassium

between blood and tissue cells in acidosis and in postacidotic periods of recovery have profound effects on cardiac and skeletal muscle. In acidosis, potassium is liberated from cells, most in the urine if renal function is adequate, or increased in concentration in the blood if renal function is impaired. In the postacidotic period of recovery after acidosis has been corrected, avid uptake of potassium by the cells may result in hypopotassemia. Both hyperpotassemia and hypopotassemia have characteristic effects on the electrocardiogram, and hypopotassemia may result in weakness or paralysis of skeletal muscles.

A relatively few mechanisms are responsible for gross alterations in concentrations of the principal electrolytes in blood plasma. Hyperelectrolytemia and hyperosmolarity of the blood plasma in infants and children may develop under conditions associated with severe water deficit. The concentrations of carbon dioxide and its anion  $\text{HCO}_3^-$  in the blood are governed mainly by respiratory exchange in the lungs. The concentrations of the other electrolytes are governed by their ingress or egress by way of the gastrointestinal tract, kidneys and, to some extent, the skin. Disturbances in the functions of each of these organs may be primary causes of derangements in the electrolyte structure of the body fluids.

## CLINICAL DISTURBANCES\*

### DEHYDRATION

The body suffers from lack of water more quickly than from lack of any other nutrient except oxygen. This is an especially important problem in infancy, in which the requirements for water exchange in proportion to body weight are far greater than in adult life, and fluid balances are more easily disturbed under abnormal conditions. Thus, as Gamble pointed out, the daily intake and output of water is about 700 ml. in an infant weighing 7 kg. whose extracellular fluid is in the range of 1400 ml., in contrast to a daily intake and output of about 2 liters in an adult weighing 70 kg. whose extracellular fluid averages about 14 liters. Normally, fluid balances are maintained despite wide variations in the daily intake and excretion of water and metabolites. These balances are soon disturbed when there is too great a disparity between intake and total expenditure of water or when

abnormal conditions lead to excessive loss or retention of salts.

Depletion of body water in states of dehydration encountered clinically may be initiated by lack of either water or salts or, as is usually the case, of both. Dehydration most often occurs as a consequence of losses in vomiting, diarrhea or diabetic acidosis, but lack of water in itself may be a primary cause of dehydration when there is an inadequate intake of water to cover the obligatory needs for renal excretion, or when there is excessive loss of water vapor from the lungs and skin, as with fever and hyperpnea. Under such conditions impairment of renal function is usually a primary factor or, owing to hemoconcentration, a secondary one.

In severe dehydration, with or without acidosis or alkalosis, oliguria develops; thirst may be present, but is by no means constant. Physical signs are loss of weight, grayish pallor, dryness, inelasticity and diminished turgor of the skin, dryness of the mucous membranes, sunken fontanels in infants, retracted abdomen and collapsed superficial veins. Fever may be due to the dehydration as well as to an attendant infection. Hemoconcentration may be manifest by an elevated volume of red blood cells or by an increased red blood cell count and increased concentration of the serum proteins. These data are not dependable when there is anemia or protein deficiency.

### ACIDOSIS AND ALKALOSIS

**General Considerations.** In clinical usage the term "acidosis" denotes conditions caused by accumulation in the body of an excess of acids (i.e., anions) or by excessive loss of bases (i.e., mineral cations); the term "alkalosis" denotes conditions caused by accumulation in the body of an excess of base or by excessive loss of acid. These conditions are described as *metabolic* when the disturbances arise from faulty intake or output of bases or of acids other than carbonic acid. They are described as *respiratory* when ascribable to disturbances in the respiratory control of the carbon dioxide content of the blood.

In both metabolic and respiratory types of acidosis and alkalosis the terms "compensated" and "uncompensated" are used to denote whether or not the pH of the blood is maintained within normal limits by the buffer systems and physiologic mechanisms that govern the concentrations of different components of the electrolyte system.

When the concentration of blood bicarbon-

\* Parenteral fluid therapy in the treatment of fluid and electrolyte disturbances is detailed in the section beginning on page 183.

FIG. 34. Nomogram with lines drawn to indicate simultaneously occurring values for bicarbonate, pH and carbon dioxide tension in the blood plasma in normal conditions and in acidosis and alkalosis. A straight line drawn across the chart indicates simultaneously occurring values: thus, if the carbon dioxide content and pH values are known, a line drawn through those 2 values indicates the carbon dioxide tension. (N.B. For  $\text{CO}_2$ , 1 mM. = 1 mEq.) (Adapted from the line chart in Peters and Van Slyke: Quantitative Clinical Chemistry, Vol. 1.)

ate is decreased in metabolic acidosis, central control of the pulmonary mechanism normally leads to an increase in rate and amplitude of respirations (hyperpnea), thereby increasing the removal of carbon dioxide and decreasing its tension in the blood. Conversely, when the blood bicarbonate is increased in metabolic alkalosis, the normal response is a reduction in rate and amplitude of respiration (apnea) until the carbon dioxide tension is increased. In both cases the pulmonary response *tends* to bring the pH value to within normal limits by establishing a ratio approaching 1:20 between the concentrations of carbonic acid and bicarbonate.

In respiratory disturbances, when changes in carbon dioxide tension in the blood are primary, mechanisms responsible for compensative adjustments of other anions in the blood are more obscure, but appear to be governed principally by renal excretion. In respiratory

acidosis, when an excess of carbonic acid accumulates in the blood, chloride leaves the plasma, allowing more bicarbonate ions to be neutralized by sodium; in respiratory alkalosis, when the carbon dioxide tension in the blood is reduced by hyperventilation, the bicarbonate is reduced by a decrease in concentration of sodium and/or an increase of chloride in the plasma.

The fixed relationships among values for bicarbonate, pH and carbonic acid in the blood plasma are expressed in the Henderson-Hasselbalch equation:

$$\text{pH} = 6.1 + \log \frac{\text{BHCO}_3}{\text{HHCO}_3}$$

Figure 34 represents these relationships in a nomogram based on that equation. Data in Table 30 similarly illustrate the relationships among values for bicarbonate, pH and carbon dioxide tension of the plasma characterizing

each of the four categories of acidosis and alkalosis in uncompensated states, and the adjustments in these values postulated as occurring with compensation in each state. Complete compensation, within the meaning of the term here indicated, is rarely attained except in mild disturbances; in pathologic conditions the pH of the blood usually is changed in the same direction from normal as the bicarbonate changes in metabolic acidosis and alkalosis, and in the reverse direction from those of the bicarbonate in respiratory acidosis and alkalosis. Metabolic disorders affecting the blood electrolytes may occur concomitantly with conditions of disease leading to respiratory acidosis or alkalosis. Secondary disturbances in respiratory control of the carbon dioxide tension in the blood may complicate the pictures of metabolic acidosis and alkalosis, leading to changes of pH and carbon dioxide of the blood in directions opposite to those of the primary disturbance.

#### METABOLIC ACIDOSIS

The type of acidosis most frequently encountered is metabolic acidosis. It occurs in severe diarrheal states, especially in infants,

and in diabetes, nephritis, starvation, dehydration and practically all moribund states. It may result from increased production of acid metabolites in the body, from ingestion of acids or acid-producing salts (e.g., ammonium chloride) or from failure of the kidneys to excrete anions as rapidly as they accumulate in the blood. It may also result from excessive losses of mineral cations and bicarbonate in diarrhea. In conditions such as these, dehydration and acidosis are closely interdependent, each aggravating the other. Acidosis leads to increased excretion of mineral cations (sodium and potassium), partly because the excretion of excessive amounts of acids in the urine necessitates increased excretion of cations beyond the power of the kidneys to form ammonia for the economy of mineral cations, and partly because acidosis increases cellular catabolism, liberating potassium. Such losses of mineral cations from the body are additive factors in the development of dehydration and, when the mineral cations are excreted as buffer salts (e.g., phosphates), are an added cause of acidosis. Darrow suggests that with infantile diarrhea, in patients suffering from deficits of potassium, water,

Table 30.  $\text{H}_2\text{CO}_3\text{—BHCO}_3$  Buffering of Blood Plasma in Different States of Acidosis and Alkalosis

	Carbon Dioxide in Plasma				pH
	BHCO <sub>3</sub>		H <sub>2</sub> CO <sub>3</sub>	CO <sub>2</sub> Tension	
	mEq./L.	Vol./100 Cc.	mEq./L.	Mm. Hg	
Normal range . . . . .	22-30	50-65	1.1-1.5	35-50	7.35-7.45
1. Metabolic acidosis					
(a) Uncompensated . . . . .	15	33	1.35	45	7.14
(b) Compensated . . . . .	15	33	0.75	25	7.4
2. Metabolic alkalosis					
(a) Uncompensated . . . . .	45	100	1.35	45	7.6
(b) Compensated . . . . .	45	100	2.28	76	7.4
3. Respiratory acidosis					
(a) Uncompensated carbon dioxide excess . . . . .	27	60	2.28	76	7.16
(b) Compensated carbon dioxide excess . . . . .	45	100	2.28	76	7.4
4. Respiratory alkalosis					
(a) Uncompensated carbon dioxide deficit . . . . .	27	60	0.75	25	7.65
(b) Compensated carbon dioxide deficit . . . . .	15	33	0.75	25	7.4

Adjustments postulated as occurring with compensation in the various states of acidosis and alkalosis: (1) *metabolic acidosis* (a) with normal carbon dioxide tension, bicarbonate deficit and lowered pH, and (b) the decreased carbon dioxide tension required to bring the pH to normal with the bicarbonate deficit unchanged; (2) *metabolic alkalosis* (a) with normal carbon dioxide tension, bicarbonate excess and elevated pH, and (b) the increased carbon dioxide tension required to bring the pH to normal with the bicarbonate excess unchanged; (3) *respiratory acidosis* (a) with normal carbon dioxide tension, bicarbonate deficit and lowered pH, and (b) the increase of bicarbonate required to bring the pH to normal with the increased carbon dioxide tension unchanged; (4) *respiratory alkalosis* (a) with normal carbon dioxide tension, bicarbonate excess and elevated pH, and (b) the decrease of bicarbonate required to bring the pH to normal with the decreased carbon dioxide tension unchanged.

sodium and chloride, shifts of sodium from extracellular to intracellular fluids may lead to states of acidosis with low levels of sodium in the plasma in relation to those of chloride. With dehydration, decreased volume and increased viscosity of the blood result in inadequate circulation and lead to increased production of metabolic acids, owing to poor oxygen exchange in the tissues and to retention of metabolites following diminished renal output.

Ketonuria may occur with or without a state of acidosis. Ketonuria frequently accompanies severe vomiting, especially in infants and children. Accumulation of ketone acids in the blood in conditions associated with severe vomiting may balance the losses of chloride and prevent what would otherwise be a state of alkalosis with hypochloremia (e.g., in intestinal obstruction).

**Symptoms.** The symptoms of metabolic acidosis vary. Hyperpnea may be evident when the bicarbonate is reduced to half of normal, but becomes progressively greater when the acidosis increases beyond this point. There may be increasing restlessness, headache, nausea, drowsiness, meningismus and hyperpnea until coma supervenes. In nephritic acidosis, convulsions may occur. Patients with chronic nephritis tend to adjust to a state of mild uncompensated acidosis, with lowered pH and bicarbonate of the blood, and remain relatively free from unfavorable symptoms for long periods of time. They may get along better in this state than if correction is attempted by administration of alkali.

#### METABOLIC ALKALOSIS

Metabolic alkalosis is most often associated with severe and persistent vomiting when hydrochloric acid of gastric juice is lost. It may also be caused by administration of excessive amounts of alkaline salts such as sodium bicarbonate, particularly in the presence of renal impairment.

Darrow and others have shown that metabolic alkalosis with hypochloremia may be associated with decreases of intracellular potassium and increases of intracellular sodium (probably mainly in muscle tissue) in infants with diarrheal disease and in rats rendered potassium-deficient by low potassium diets and injections of desoxycorticosterone. Such alkalosis may occur as a result of renal excretion of chloride without sodium (Berliner et al.) or of shifts of cations (hydrogen, sodium, potassium) between muscle and extracellular fluid (Darrow et al.) apart from

renal mechanisms. The repair of such alkalosis following the administration of potassium is associated with a reversed shift of potassium and sodium between muscle and extracellular fluids.

**Symptoms.** Numbness, tingling sensations, headache, stupor, tetany and convulsions may be related to the state of alkalosis. Hypocalcemic tetany is usually not accompanied by alkalosis, but alkalosis developing in a susceptible infant may precipitate tetany. Alkalosis caused by persistent vomiting is associated with dehydration, whereas alkalosis caused by excessive ingestion of alkalinizing salts often may be associated with edema.

#### RESPIRATORY ACIDOSIS

Increased carbon dioxide tension in the blood may result from conditions leading to an increase of carbon dioxide in the alveolar air, as with generalized obstructive emphysema, with pulmonary edema, with asphyxia from smothering or tracheal obstruction, with rebreathing of air in a small closed space, and in asthma. It increases somewhat more slowly after suppression of the respiratory center by drugs (e.g., morphine) or infections (e.g., poliomyelitis).

The slowing of respirations by central depression leading to respiratory acidosis must be differentiated from apnea, which may occur with metabolic alkalosis; the dyspnea of cardiac and respiratory disorders must be differentiated from the hyperpnea of metabolic acidosis. The appearance of cyanosis may serve to differentiate the dyspnea of pulmonary congestion from hyperpnea of metabolic acidosis, and respiratory paralysis from the apnea of metabolic alkalosis. The plasma bicarbonate is progressively increased in respiratory acidosis by the departure of chloride from the plasma, and the resultant hypochloremia may be confused with the hypochloremia of metabolic alkalosis brought about by vomiting. Laboratory data in such conditions must be interpreted with careful consideration of the clinical history and physical examination. Compensating adjustment (Table 30) of blood electrolytes in respiratory acidosis may lead to values for bicarbonate and carbon dioxide tension similar to values in compensated metabolic alkalosis with hypochloremia.

**Treatment.** Artificial respiration must be used in asphyxia and in respiratory paralysis and respiratory stimulants must be used to counteract the effects of overdosage with depressant drugs. Cardiac stimulants and oxy-

en may be given for congestive cardiac failure.

RESPIRATORY ALKALOSIS

transient decrease of carbon dioxide tension in the blood may result from overbreathing, either voluntary or with crying or undue excitement in infants and children, or with hysteria in older persons. Hyperventilation of longer duration, as may be induced by injections (e.g., encephalitis) or drugs (e.g., salicylates, lobeline) affecting the respiratory center, is followed by a decrease of plasma bicarbonate and an elevation of the pH value.

In the diagnosis of respiratory alkalosis the hyperventilation induced by central stimulation must be differentiated from the hypernea accompanying metabolic acidosis. Compensating adjustments of the blood electrolytes in respiratory alkalosis lead to values for bicarbonate and carbon dioxide tension in the plasma similar to those in compensated metabolic acidosis (Table 30). For the differential diagnosis of such states the determination of

the pH of the plasma may be the most valuable laboratory test, since this determination permits calculation of the carbon dioxide tension.

ELECTROLYTE STRUCTURE OF THE BLOOD  
PLASMA IN VARIOUS DISTURBANCES

The data in Table 31 have been assembled to provide a perspective of the general patterns of derangements of electrolytes in various clinical disturbances. The comments which follow here may assist in securing this perspective.

A fairly satisfactory estimate of the state of the electrolytes of the blood plasma in most pathologic conditions can be obtained from three measurements: total base, bicarbonate, and chloride (Table 31).

The undetermined anions, or the remainder obtained by subtracting from the total base the sum of the bicarbonate and chloride values, are comprised of proteins, phosphates, sulfates and organic acids. A value lower than normal suggests that the

\* The data illustrate the trend of the deviations observed in the various pathologic states, but do not indicate the range of values that may be observed in varying degrees of severity of the clinical disturbances.

concentration of proteins is low, as in nephrosis (item 6). Values above normal signify failure of renal excretion and accumulation of acid metabolites. Thus the decrease of bicarbonate in nephritic acidosis is caused mainly by an increase of the metabolic anions, although a decrease in total base may be contributory (item 5); also in dehydration from any cause diminished renal output is responsible for retention of acid metabolites and consequently a decrease in bicarbonate.

A more accurate estimate of the undetermined anion fraction can be made if the concentration of the plasma proteins is known; determination by the falling drop method or by the copper sulfate method is adequate. The anion equivalence of the proteins is calculated as milliequivalents per liter by multiplying the grams of protein per 100 ml. by 2.43. Subtraction of the value for protein equivalence from the anions listed in Table 30 as undetermined anions would then give a closer accounting of the anions that increase with renal disability.

In *metabolic acidosis and alkalosis* the ketosis of fasting (item 2) offers an example of reduction of plasma bicarbonate by an increase of organic anions, with little other change in the electrolyte structure. In diabetic acidosis (item 3) the reduction of plasma bicarbonate is caused both by a large accumulation of the ketone acids and by a decrease in concentration of total base that results from urinary excretion of sodium and potassium. With increasing dehydration there is an increase of acid metabolites other than ketone acids, ascribable to failing renal excretion. With intestinal obstruction and vomiting the accumulation of ketone acids in the blood (from fasting) may mask what would otherwise be a state of alkalosis induced by losses of chloride (item 10).

In gastrointestinal disturbances, losses of electrolytes by vomiting and diarrhea lead to dehydration. If there is diarrhea without vomiting, acidosis develops with a lowered concentration of total base and little reduction of chloride (item 4); if there is vomiting and little diarrhea, hypochloremia and alkalosis are likely to develop (items 8, 9). If sodium and chloride are lost equally, neither acidosis nor alkalosis may develop until dehydration leads to renal retention with an increase of acid metabolites and acidosis.

Chloride acidosis (item 7) is an example of reduction of plasma bicarbonate by accumulation of mineral anions in the blood. It may be caused by ingestion of ammonium chloride or calcium chloride. In infants with diarrhea, chloride acidosis may be caused or

aggravated by administration of sodium chloride solution for the treatment of dehydration, when the administered sodium is lost with continuing diarrhea and the chloride ions accumulate in the body.

Alkalosis from ingestion of large doses of sodium bicarbonate (item 11) is especially liable to develop when renal function is impaired or if insufficient water is available for renal excretion of the excess sodium bicarbonate. Such retention of bicarbonate may result in edema. If cardiac decompensation with pulmonary edema is superimposed, there is retention of carbon dioxide with an increase in concentration of bicarbonate in the plasma and a corresponding decrease in the chloride level. If these changes are sufficient, the electrolyte disturbance may shift to a respiratory acidosis (item 12). Such conditions can be differentiated only by determination of the pH and carbon dioxide tension of the plasma.

*Respiratory acidosis* occurs most commonly in association with pulmonary edema and with generalized obstructive emphysema (items 12, 13). An increase of carbon dioxide tension in the blood is followed by a decrease in concentration of chloride in the plasma, leaving cations to neutralize the accumulating carbonic acid.

The examples of *respiratory alkalosis* (items 14, 15, 16) illustrate changes occurring with prolonged hyperventilation caused by encephalitis and by salicylism. The resulting carbon dioxide deficit is followed by a decrease of bicarbonate, which is accounted for by a decrease of sodium or an increase of chloride in the plasma, or both.

States of hyperelectrolytemia and hypoelectrolytemia (items 17, 18) may result from water deprivation (especially with fever and high environmental temperature) or from excessive losses of water vapor from the body as with hyperventilation. The magnitude of ventilatory losses of water vapor is demonstrable by measurements of insensible weight loss. This rate, normally around 1 gm. per hour per kilogram of body weight in infants, may rise threefold or fourfold with severe hyperventilation.

## SHOCK

The term "shock" is applied to a syndrome of circulatory collapse and attendant disturbances that may result from physical injury (especially with hemorrhage, crushing injuries of the trunk and extremities, surgical operations, and burns) and from disease. In infants and small children shock, except as associated with birth, is more frequently encountered in severe illnesses, such as diarrheal disorders, than in injuries.

**Causes.** The most important factor in the development of shock appears to be a reduction in effective blood flow through the tissues, resulting in tissue anoxia and impaired removal of cellular metabolic products. A reduction in circulating blood volume may result from functional failure of the cardiovascular system and/or from losses of blood from the circulation. A decreased volume of blood in the circulation may result from hemorrhage, either external or internal, from loss of plasma, such as occurs after burns, or from general dehydration of the body as with severe vomiting and diarrhea or with diabetic acidosis. In infections and after burns the development of shock may be aggravated by toxic effects on the nervous system, the adrenal glands, the heart and other organs. Anuria resulting from circulatory failure and/or dehydration may be a serious complication of a prolonged state of shock.

Pre-existing nutritional deficiencies (malnutrition, anemia, hypoproteinemia or dehydration) favor the development of shock. Since infants normally have a more labile and unstable fluid balance than adults and more

commonly suffer nutritional deficiencies, it is especially important that preventive measures be taken early in the treatment of any condition in which shock may develop.

**Clinical Varieties.** Shock is characterized by extreme weakness, cold clammy skin, grayish pallor, cyanosis, rapid pulse, low blood pressure, thirst and eventual loss of consciousness; if prolonged, it results in death.

**Syncope.** So-called neurogenic shock with temporary loss of consciousness may develop from reflex vasodilatation and slowing of the heart after physical injury, pain, fright or other emotional stress (see also p. 1127). With crushing injuries or with burns transient primary shock may be followed by secondary shock induced by such factors as loss of blood or extravasation of plasma.

**Shock due to loss of blood or plasma.** Reduction of blood volume by 30 to 40 per cent leads to a profound state of shock that will end fatally unless restorative procedures follow quickly. For a short time after the blood volume has been reduced to a dangerously low point, intravenous infusion of whole blood or of a blood substitute (e.g., plasma; saline and glucose solutions; dextran or gelatin) in sufficient amount to restore the circulating blood volume may prevent death, but such treatment is ineffective if delayed.

The severity of shock due to hemorrhage depends upon the rate of bleeding and the amount of blood loss. If the rate is sufficiently slow, vasoconstriction and the passage of tissue fluids into the blood serve to compensate the loss of blood and may afford an

adequate volume of circulating fluid for a considerable time. Prior to circulatory collapse, the blood pressure is not a reliable index of impending shock. With the entrance of tissue fluid into the circulation the percentile volume of plasma increases; this change is designated "hemodilution."

After burns and crushing injuries of soft tissues the escape of blood plasma into and from the surfaces of injured tissues leads to a reduction of blood volume with an increased percentile volume of cells in the blood; this change is designated "hemoconcentration." The increased viscosity of the blood slows the circulation through the capillary beds and thus increases anoxia of the tissues.

**Shock due to infections, dehydration and other systemic disturbances.** In a variety of diseases many concomitant factors may contribute to circulatory collapse. In diabetic acidosis the increased excretion of electrolytes (sodium and potassium) in the urine results in progressively greater dehydration, with decreased blood volume and hemoconcentration. Loss of electrolytes in vomitus and stools in infants leads to a similar state of severe dehydration with hemoconcentration, and the concomitant development of acidosis increases the loss of electrolytes. With acute peritonitis a state of shock may develop, owing to the loss of plasma into the peritoneal exudate and to losses of fluid and electrolytes by vomiting or by accumulation of fluids within partly obstructed loops of bowel. With some infections, especially toxemia causing myocardial damage, circulatory failure may be responsible for a decreased rate of effective blood flow without a decrease in the total volume of blood.

**Treatment.** The immediate treatment of shock, as well as its prevention, should be directed primarily to the maintenance of normal blood circulation and to the correction of pathologic changes in the blood. In case of injuries, hemorrhage must be arrested, pain should be relieved by appropriate sedatives, and the patient should be kept quiet in "shock position," i.e., with head low and feet slightly elevated. The type and amount of fluids required for restoration of a depleted blood volume will depend on the conditions leading to the shock state. Thus, after hemor-

rhage or skeletal injuries, with hemodilution transfusion of whole blood is needed; whereas, after burns or crushing injuries of soft tissues, with hemoconcentration, plasma is needed rather than whole blood. In either case, saline and glucose solutions may be used in addition to, but not in place of, blood or plasma. In shock associated with dehydration solutions of sodium chloride and of sodium bicarbonate or sodium lactate to restore electrolytes and to correct acidosis should be given according to need. Potassium-containing solutions are contraindicated until renal function is adequately established.

Laboratory tests are necessary to guide such therapy properly, but, in the absence of laboratory facilities, closely observed objective signs must be depended upon in emergencies. The state of collapse of superficial veins is a dependable sign of low venous pressure and diminished circulating blood volume. Determinations of hemoglobin, the hematocrit value, the red blood cell count and plasma protein afford indices of hemodilution or hemoconcentration; in infants and young children these indices are less dependable than in older persons, since such values may have been abnormally low, owing to pre-existing nutritional deficiencies.

For the treatment of severe dehydration and acidosis associated with infections, gastroenteritis and diabetic acidosis see page 18.

The application of heat or cold to the patient in shock may be harmful. In experimental animals the survival rate from comparable states of shock has been higher at environmental temperatures of 70° to 72° (room temperatures) than at temperatures significantly above or below this level. Reasons for the higher fatality rate at lower temperatures are not clear; at higher temperatures it may be ascribed to vasodilatation, and at temperatures as high as 95° F. to increase in the insensible water loss. Elevation of body temperature also increases the basal metabolic rate, resulting in a demand for increased oxygen consumption. It would appear that merely covering the patient with a light blanket or sheet would be adequate provision for thermal regulation.

GEORGE M. GUN

# PARENTERAL FLUID THERAPY

The preceding sections have outlined the chemical anatomy of the body and the physiologic mechanisms regulating body composition. This section presents a practical application of such principles to specific problems of fluid therapy.

Fluid therapy should be viewed from four aspects: (1) *deficit therapy*, which is concerned with the normalization of the volume of body fluids (water) and of the concentration of solutes (usually electrolytes) in them. Such therapy supplies water and electrolytes to replace deficiencies resulting from inadequate intake in the presence of usual losses as in thirsting and fasting or from excessive losses in the presence of usual intake as in diarrhea or diabetic acidosis; (2) *maintenance therapy*, which is concerned with administration of water and solutes in quantities approximating those lost from the body under usual circumstances; (3) *the concomitant replacement of abnormal losses*, which applies water and electrolytes to meet losses occurring in the particular disease states under treatment. These losses may be from the body as a whole (external abnormal losses, such as gastric drainage) or may represent sequestration of water or solutes, or both, in certain regions of the body (internal abnormal losses, such as pleural effusion). The replacement of abnormal losses represents a special phase of maintenance therapy, but must be separately quantitated. (4) *Supplemental therapy*, which is concerned with the supply of water and solutes over and above the usual requirements for maintenance and for replacement of abnormal losses, to facilitate a specific physiologic function, such as alkalization of the urine or induction of diuresis.

## DEFICIT THERAPY

**General Considerations.** Disturbances in body composition may result from reduced intake in the presence of usual losses or from excessive losses with or without the usual intake. The severity of the disturbance depends on the relation between intake and output and the magnitude of the body reservoirs. Infants frequently exhibit decreased appetite with disease and have limited capacities to reduce the usual loss of water in the urine. On the other hand, the volume

of water and the quantity of available sodium and chloride per unit of body weight are greater in the infant than in the adult. Deficit therapy must be based, therefore, on an appraisal of the relative changes in body composition. Such an appraisal must rest largely on clinical evaluation of the patient by means of an accurate history and precise physical examination. Table 32 lists the historical data which should be elicited in every problem involving fluid therapy.

Of particular importance in judging the magnitude of deficits in infants is change in weight. Losses in excess of 1 per cent of the body weight per day represent loss of body water. The precise composition of the infant's feeding mixtures also permits some assessment of the water and electrolyte balance. Home-made electrolyte mixtures for the oral treatment of diarrhea are often responsible for severe hyperosmolarity, owing to failure of the mother to follow precisely the directions of the physician. The time and frequency of recent urinations, whether excessive or suppressed, may provide some appreciation of the severity of dehydration. Frequent and excessive urination is suggestive of diabetes mellitus. Usual output in association with physical signs of dehydration suggests a loss in capacity of the kidney to conserve water.

The physical signs of disturbances in body composition are of even greater value than the historical data in the planning of fluid therapy (Tables 33, 34). Some of the signs listed in Table 33 are not specific for dehydration, but are characteristic of shock, which frequently accompanies dehydration. In the well nourished older infant and child,

skin turgor may remain fairly normal in the presence of dehydration. The clinical determination of isotonic, hypertonic or hypotonic dehydration is usually not as definitive as may be suggested by Table 33. When findings are marked, differentiation may be possible, but borderline findings, such as somewhat dry mucous membranes and somewhat poor skin turgor, cannot be interpreted as confirming the presence of disturbances in osmolarity.

The physical findings which characterize variations in the concentration of specific substances in the blood (Table 34) require some explanation. The characteristic signs of acidosis are increased depth and rate of respiration, which, however, may be depressed markedly in the presence of severe circulatory insufficiency. The compensatory diminution in breathing that is associated

with alkalosis is usually absent in adults, marked in infants with pyloric stenosis. deficiencies of other electrolytes, such as potassium, may exist without obvious physical findings. Hypokalemia may not always be present even when cells are depleted of potassium. Such deficits are recognized by history alone.

Certain laboratory data (Table 35) are helpful in the initial planning of therapy. None is so essential that adequate therapy cannot be initiated without it. Of great importance is the use of the laboratory in assessing the results of deficit therapy in guiding subsequent maintenance therapy. The carbon dioxide content usually indicates the degree of acidosis or alkalosis, except in respiratory disturbances. It is rarely necessary to know the pH of the blood to determine whether the disturbance is metabolic or respiratory in origin. The sum of carbon dioxide content and chloride concentration plus 15 approximates the sodium concentration, except in the presence

etosis. The sodium concentration can, however, be determined directly in most hospitals by means of the flame photometer. The serum sodium level is of particular importance in determining the loss of water in relation to that of electrolytes. Hypernatremia indicates excessive loss of water in relation to electrolytes; hyponatremia indicates excessive loss of electrolytes in relation to water. The serum potassium concentration at the beginning of therapy is not particularly helpful, since it may be elevated, owing to hypoxia, diminished renal function or acidosis even in the presence of significant cellular deficits. Measurement of the blood urea nitrogen or nonprotein nitrogen is helpful in following the progress of therapy, a rising blood urea nitrogen indicating either intrinsic renal injury or continuing circulatory insufficiency. The level of plasma protein and the hematocrit value have limited usefulness at the beginning of therapy, but the initial determinations are of considerable help in assessing the effects of therapy. When correlated with physical findings, they may be useful in planning therapy. For example, when there is a low or even normal hematocrit value with signs of dehydration, anemia must be present which should be corrected during deficit therapy. Serial determinations of the hematocrit value and the plasma protein concentration of capillary blood using a refractometer are essential in following the course of patients with burns. Measurements of urinary output, specific gravity, albuminuria, glycosuria and ketonuria are valuable in assessing the degree of renal compensation which may be expected during therapy, as well as in guiding therapy in diabetic acidosis.

Serial electrocardiograms may provide clues of disturbances in concentration of such electrolytes as potassium and calcium. Leads 2 and aV<sub>5</sub> are particularly useful for this purpose (see p. 830).

The quantities of water and electrolytes which may be lost in various conditions (Table 36) have been obtained by a variety of techniques, such as recovery balance studies, isotope dilution methods, tissue and whole body analyses and animal experiments. They represent *only an order of magnitude* and serve as a partially quantitative guide rather than as a precise determinant of therapy. It can be seen from Table 33 that there is a decided similarity in the magnitude of the deficits, despite the fact that the precipitating conditions vary widely. This situation is not surprising, since the deficits

are related to readjustments as well as to the direct losses. Loss of chloride in the vomitus in pyloric stenosis, for example, leads to an increase in excretion of sodium and potassium in the urine. Thus deficits of these cations will result even though the original losses of them in the vomitus were relatively small. Similar compensatory losses are seen in diarrhea and other conditions. This fact justifies a similar therapeutic approach, with only minor modifications, to a variety of conditions.

In planning deficit therapy the physician must be aware that circulatory insufficiency and renal dysfunction are of primary importance in the morbidity and mortality of dehydration. Consequently the initial step is aimed at improving circulatory dynamics and renal function. Restoration of these functions depends on rapid expansion of extracellular volume with a fluid such as Ringer's lactate, which resembles the extracellular fluid and remains completely in this compartment. Such solutions are preferentially administered intravenously, although some improvement may result from subcutaneous injection. However, solutions of glucose in water or in dilute saline solutions must not be administered subcutaneously. Shock can be precipitated by the rapid migration of salt and water into the subcutaneous pool as glucose slowly diffuses into the vascular compartment. Circulatory insufficiency due to dehydration should not be treated by the immediate administration of blood, owing to the possibility of thrombosis and renal tubular injury from minor degrees of blood incompatibility. Blood should be given for shock associated with dehydration

only after the extracellular volume has been rapidly expanded. The intracellular deficits of water and electrolytes must be replaced slowly and only after improvements in circulation and renal functions have been effected.

DEFICIT THERAPY IN SPECIFIC CONDITIONS

**Fasting and Thirsting.** One of the commonest problems requiring fluid therapy is the initial treatment of the infant or child who has taken little or no water and food for periods of one to five days. Inspection of Table 36 indicates that such infants are deficient not only in water, which has evaporated from the lungs and skin, but also in electrolytes, particularly in sodium and chloride, which have been excreted in the urine. The administration of electrolyte-free

solutions under such circumstances leads to an increase in urine volume with possible increased losses of electrolytes and may actually increase the dehydration. If fasting and thirsting continue beyond four or five days, urinary output will fall to such a level that there will be no significant continued loss of electrolytes, and severe deficiency of water alone will result.

Therapy (Table 37) is begun with administration of Ringer's lactate solution to produce rapid and safe expansion of extracellular volume and improvement in renal function. A large part of the remaining deficiency of water and electrolytes may be made up by a solution containing calcium lactate, sodium chloride, some potassium and potential bicarbonate, such as lactate.

or acetate. Children and adults should be given approximately one fourth to one third less water and sodium per kilogram of body weight than infants for a given degree of clinical dehydration, owing to the relatively smaller extracellular reservoirs with increasing age. Potassium deficits are relatively the same in infants, children and adults, since there is approximately the same quantity of potassium per kilogram of body weight in such patients. When deficit therapy is planned, correction of the body weight toward ideal weight should also be made in the presence of obesity. Water, carbohydrate and electrolytes may be administered to the mildly ill patient by mouth. Infants, however, often vomit when they are dehydrated, and for this reason initial therapy is usually given parenterally. After completion of the deficit therapy the patient should be sustained on a maintenance basis as outlined on page 192.

**Acute Diarrhea.** Despite improved infant care, diarrhea continues to be a serious problem in many areas of the world. The physical signs which result are principally those outlined in Tables 33 and 34. As indicated in Table 36, diarrhea results in large losses of water and electrolytes in varying proportions. In approximately 70 per cent of instances there is isotonic dehydration in which the losses of water and electrolytes are equivalent, so that total solute concentration in body fluids remains fairly normal even though there may be severe acidosis.

**Isotonic dehydration.** The therapy outlined in Table 37 is based upon the principle that extracellular volume must be restored first in order to improve circulation and renal function. Administration of an approximately isotonic fluid, such as Ringer's lactate solution, for a short time expands extracellular volume effectively and leads to improvement in solute concentration, whether the sodium concentration is elevated or low. The balance of the deficit of extracellular water and electrolytes and the beginning of correction of the intracellular deficit of potassium and water are carried out slowly over a subsequent six- to eight-hour period. After this deficit therapy, usual maintenance therapy is begun, and in addition enough water, sodium, chloride and potassium is administered to approximate the continuing abnormal losses in the stool. It can be seen that the deficit therapy outlined for diarrhea does not differ greatly from that for fasting and thirsting, nor from that for diabetic ketosis,

and differs only in a minor way from the therapy for pyloric stenosis. This plan does not represent the only approach to the treatment of diarrhea, but serves as a framework upon which modifications may be made.

**Hypertonic dehydration.** Although this condition is less common (approximately 20 per cent of cases of diarrhea) than isotonic dehydration, it occurs frequently in young infants in whom conservation of water by the kidney is limited and particularly when the renal solute load is high, as when boiled skimmed milk is fed to infants with diarrhea. Hypertonic dehydration may also result from administration of solutions of high electrolyte concentration, such as home-made or commercial salt and water mixtures. High environmental temperatures and hyperventilation also significantly increase evaporative losses of water. Obviously attempts should be made to avoid all these circumstances in infants with diarrhea.

Physical signs of hypertonic dehydration are listed in Tables 30 and 31. Of particular importance are the cerebral changes which result from severe hyperosmolarity. The exact cause of these changes is unknown, but there is usually an elevated protein level in the cerebrospinal fluid. Hypocalcemia has occasionally complicated hyperosmolarity (Finberg and Harrison). It can be prevented in experimental animals by administration of potassium. Marked hypocalcemia has not been observed in the author's clinic, in which administration of potassium is part of the routine therapy of diarrhea. The cerebral symptoms have been attributed to too rapid reduction of the serum sodium concentration even though the sodium level may still be above normal. However, seizures have been observed in children recovering from hypertonic dehydration when no significant change in extracellular osmolarity had been effected by treatment. It is possible that the convulsions represent a response to damage from the hyperosmolarity and from hyperthermia. The cerebral changes may be permanent and be one of the causes of acquired cerebral palsy.

Balance studies reveal a slight deficiency of sodium, but an excess of chloride and a relatively minor deficit of potassium. Serum potassium, however, frequently falls to low levels during therapy unless potassium is administered. Characteristically, whether treatment consists of large amounts of water with or without salt, there is expansion of extracellular volume with the development

of significant edema and at times of cardiac failure before there is any notable excretion of chloride and correction of the acidosis.

The therapy for hypertonic dehydration (Table 37) represents some deviation from the usual therapy of diarrhea. The principles are essentially the same, however: namely, rapid expansion with extracellular fluid to improve circulation followed by *slow* replacement of intracellular water and electrolytes. The intake of chloride is minimized. Changes in concentration should be effected slowly, whereas changes in volume may be effected more rapidly. In this scheme of therapy, water is administered rather slowly after the initial improvement of circulation and renal function. Intravenous administration of calcium may occasionally be required. Digitalization is indicated when there is hepatomegaly or rales as evidence of pulmonary congestion. Administration of phenobarbital may minimize the occurrence of seizures. If seizures occur which do not respond to usual anticonvulsant therapy and are not the result of hyperpyrexia, 3 per cent sodium chloride (3 to 5 ml. per kilogram) may be given intravenously. The cause of some seizures has been attributed to relative water intoxication even though the serum sodium has been reduced only 5 to 10 mEq. per liter and is still considerably above normal. Such an assumption has not been proved.

**Hypotonic dehydration.** At times, and particularly in bacillary dysentery in children, large amounts of electrolytes may be lost in the stool. Consequently hypotonic dehydration (10 per cent of all cases of diarrhea) may result and be accentuated if only electrolyte-free fluids are taken by mouth. The serum sodium concentration may be lowered to less than 130 mEq. per liter. Under these circumstances the basic plan of therapy is modified by administering relatively less glucose in water and relatively more glucose in electrolyte-containing solutions (Table 37) so that gradual correction of concentration is accomplished as volume is expanded. No attempt is made to elevate abruptly the sodium concentration by administration of hypertonic saline solution unless symptoms of water intoxication, such as convulsions, are present. Delay in administration of potassium is necessary, owing to the frequency of hyperpotassemia in association with hypotremia.

**General considerations in treatment of diarrhea.** In addition to replacement of the deficits of water and electrolytes in the treat-

ment of diarrhea, efforts must be made to obtain an etiologic diagnosis so that specific chemotherapy may be given if indicated (see p. 655). There are no aspects of chemotherapy that affect fluid therapy except during the administration of sulfonamides; adequate amounts of fluid for urine formation must be provided.

The maintenance of fluid balance in a patient with diarrhea (see p. 187) requires an excess of water and electrolytes for stool formation. The extent of the losses range from 40 to 400 ml. per day in infants and 100 to 1000 ml. in children. These losses may be replaced by equal parts of 5 per cent glucose in water and Darrow's K lactate or similar commercially available solutions.

Drugs which inhibit peristaltic activity such as methylcellulose derivatives which absorb intestinal contents and produce a more bulky stool have relatively little effect on the course of infantile diarrhea.

Although the net absorption of carbohydrate, fats and proteins may be increased by feeding large amounts of milk during diarrhea, there is unquestionably an increase in the volume of stool which makes the replacement of water and electrolytes exceedingly complicated and extends the need for parenteral fluids over several days.

With complete starvation of the patient with moderately severe diarrhea, frequency and volume of stools will usually subside rapidly within forty-eight hours. When this occurs, and in the absence of gastric distention and vomiting, glucose, carbohydrate and electrolyte mixtures may be started by mouth. Mixtures of carbohydrate and electrolyte, such as Lytren, are available commercially, or a home-made mixture\* may be prescribed. Every effort should be made to guarantee that the mother does not make up mixtures more concentrated than recommended, since hypotonicity may result. When the infant tolerates the carbohydrate and electrolyte mixture by mouth without exacerbation of diarrhea, the caloric intake may be increased gradually by the substitution of mixtures which also contain fat and protein until the usual dietary intake is achieved in six to eight days. Premature administration of a large

\* Example of a sugar and electrolyte mixture for oral administration:

	Final Concentration
Sucrose . . . . . 50.0 gm.	Sucrose . . . . . 5 gm./%
NaCl . . . . . 1.7 gm.	NaCl . . . . . 30 mM./%
KHCO <sub>3</sub> . . . . . 2.0 gm.	KHCO <sub>3</sub> . . . . . 20 mM./%
Dissolve in 1 quart H <sub>2</sub> O	

number of calories in the form of milk may induce exacerbation of the diarrhea. In the young infant with a family history of allergy the use of a hypoallergenic feeding mixture, such as Nutramigen or a soy bean mixture, is recommended for the recovery phase from diarrhea, since permeability of the gastrointestinal tract to whole protein may be increased during this time. During the period of reduced caloric intake (30 to 80 C. per kilogram) the feeding mixture may be made up in an electrolyte-containing solution, such as Lytren, instead of in distilled water, to ensure adequate electrolyte intake to balance possible abnormal losses.

**Therapy of mild diarrhea.** Many infants and children with diarrhea do not require parenteral fluid therapy. The decision for the use of oral rather than parenteral therapy rests on clinical appraisal of the patient. If there are signs of circulatory insufficiency, lethargy, vomiting or gastric distention, intravenous therapy must be given. In the absence of these findings and in the presence of only mild signs of dehydration, mixtures of sugar and electrolytes as described above may be fed. Parenteral therapy is indicated for infants when amounts in excess of 1.5 liters per day are required to meet continued stool losses. Infants with mild diarrhea have been observed who have taken 2 to 3 liters of electrolyte mixtures orally per day with resultant increase in the volume of stools; cessation of oral intake resulted in prompt cessation of the diarrhea. Such instances are rare and do not detract from the value of oral carbohydrate and electrolyte mixtures in the prevention of severe disturbances when given early.

**Chronic Diarrhea.** When diarrhea is severe and prolonged, administration of amino acids, plasma and alcohol parenterally, in addition to carbohydrate and electrolytes, is required to sustain body reserves. Occasionally, full oral feedings are required during chronic diarrhea in addition to parenteral electrolyte therapy. In such instances allergy to milk protein should be suspected and hypoallergenic feeding mixtures administered. The use of diiodohydroxyquinoline has not been evaluated in other than mild nonspecific chronic diarrhea.

**Congenital Alkalosis of Gastrointestinal Origin.** Rarely, chronic diarrhea may be due to a congenital defect in the transport of water and electrolytes across the intestinal wall. In contrast to usual diarrhea the watery stools of such patients have a high content of potassium and chloride, and alkalosis results. The deficit therapy is analogous to that of

pyloric stenosis, but must be on a continuing basis and planned in conjunction with an adequate dietary intake of potassium and chloride.

**Pyloric Stenosis.** This condition is used as an example of the correction of deficits associated with alkalosis. The therapy (Table 37) differs little from that of diarrhea, except for the substitution of solutions which contain relatively more chloride in relation to sodium and potassium (NaCl and KCl), thereby permitting replacement of the relatively larger deficit of chloride with some correction of the alkalosis as volume is expanded. Correction of the hypochloremia by administration of ammonium chloride without correction of the deficit of potassium leads to continued alteration in function of renal tubular cells as well as other cells. Although deficits may be replaced and serum levels returned to normal within twelve hours, operation should not be performed for at least thirty-six to forty-eight hours to permit optimal readjustment of body functions, except in very mildly ill infants with no signs of dehydration. Adequate fluid therapy prevents deterioration during this period of preparation, and the stomach may be decompressed by gentle suction. (See page 195 for preoperative, paraoperative and postoperative therapy.)

**Diabetic Acidosis** (see also p. 1209). The deficit therapy of diabetic acidosis (Table 37) approximates that of diarrhea. Extracellular volume is expanded rapidly with Ringer's lactate solution. The balance of the deficit of extracellular water and electrolytes and the beginning of correction of the intracellular deficit of water, potassium and phosphate are carried out slowly over a six- to eight-hour period. A portion of the fluid (Darrow's K lactate) probably should be given subcutaneously to permit separate regulation of the intake of carbohydrate and water which is administered intravenously. In the appraisal of deficits in patients with diabetic ketosis, laboratory studies may be misinterpreted. Hypo-osmolality may be assumed erroneously on the basis of measurement of the serum sodium concentration. Extracellular osmolality may be normal or high even in the presence of a low serum sodium concentration if there is a high concentration of glucose. Blood sugar levels of 1800 mg. per 100 ml. are the equivalent of an additional 50 mEq. per liter of sodium. In addition, elevations of serum lipid and protein concentrations in diabetic acidosis may reduce the water content of the serum so that sodium concentrations per liter of serum are low

while sodium concentrations per liter of extracellular water are normal or high.

Administration of potassium fairly early in therapy of these patients is essential. A rapid fall in potassium concentration occurs shortly after administration of insulin or fructose. Such changes may produce alterations in the functioning of the heart, liver, brain and kidneys, may contribute to gastric distention and may even lead to respiratory paralysis. Changes in serum inorganic phosphate concentration during therapy are likewise striking and parallel those in potassium concentration. This fall is due primarily to cellular uptake of phosphorus as glycogen is formed. Although the significance of such changes has not been established clinically, it is the author's opinion that serum inorganic phosphorus levels should be sustained at low normal levels. For this reason a portion of the potassium is administered as the phosphate salt. No specific attempts are made initially or routinely to elevate the low carbon dioxide content and pH except by expanding extracellular volume with fluids resembling an ultrafiltrate of normal plasma (Ringer's lactate) (see p. 185). Such therapy frequently effects a significant reduction in acidosis with symptomatic improvement. If extreme respiratory distress persists, the administration of sodium bicarbonate or lactate may be indicated. The dose required may be calculated from the formula on page 191. However, there is a large reservoir of potential bicarbonate in the form of ketone acids which are metabolized with improvement in carbohydrate utilization after administration of insulin, so that bicarbonate concentration of the serum should not be elevated abruptly to more than 12 to 15 mEq. per liter.

The amount of insulin which can be given during this time varies considerably from one patient to another. Enough insulin to effect clearing of the ketosis by accelerating the utilization of carbohydrate should be given with adequate carbohydrate to prevent development of hypoglycemia. An initial dose of approximately 2 units per kilogram of body weight for severe diabetic ketosis and then subsequent doses at one- to three-hour intervals of  $\frac{1}{2}$  to 1 unit per kilogram are usually appropriate. Half of the initial dose of insulin should be given intravenously. Approximately 1 to 2 gm. of carbohydrate per unit of insulin may be necessary to prevent hypoglycemia. The aim of therapy should be the elimination of ketonemia and ketonuria, since persistence of acetoacetic acid and beta-hydroxybutyric

acid indicates diminished operation of Krebs cycle. Collection of urine at hourly intervals, preferably without resort to catheterization, is essential for modifying the dosage of insulin and carbohydrate as therapy progresses. Ordinarily in children will ketones be absent from the urine, when present in the serum in significant amounts; qualitative tests on serum are helpful in such instances. Reduction of the blood sugar to levels which avoid glycosuria (3+ to 4+ qualitative Benedict's or glucose oxidase) prevents excessive loss of water in the urine. However, reduction of the blood sugar to excessively low levels by administration of insulin without adequate carbohydrate rapidly leads to a return or exacerbation of ketosis. In children glycosuria frequently disappears before ketonuria, and hypoglycemic shock must be avoided.

Fructose is phosphorylated rapidly in the absence of insulin and can be converted to glycogen in the diabetic more rapidly than glucose. Fructose, therefore, may be given relatively early in therapy without significantly increasing total blood and urinary sugar. Rapid administration of fructose, however, produces a profound acidosis by the transfer of organic acid to extracellular fluids. In addition, fructose is probably not metabolized by the cerebral cortex, and symptoms due to hypoglycemia induced by excessive doses of insulin would probably not be relieved by fructose until it was converted to liver glycogen and thence to glucose. For these reasons the use of invert sugar is recommended to provide fructose for rapid increase in glycogen stores, and glucose for the prevention of hypoglycemia.

The parenteral administration of vitamins of the B complex is advised because of pre-existing malnutrition. Gastric aspiration early in therapy is helpful in relieving massive distention which can occur; pulmonary aspiration of vomitus is also avoided thereby. Administration of large doses of appropriate antibiotics if bacterial infection is present may rapidly improve the response of the patient to insulin therapy.

Oral feedings usually can be started cautiously within twelve to fourteen hours, and parenteral therapy may be discontinued in favor of oral carbohydrate and electrolyte mixtures or other more adequate liquid diets. It is particularly important at this time to avoid the frequent error of omitting necessary small doses of insulin, which must be given at intervals of six hours during the ensuing twelve to twenty-four hours.

## THERAPY OF DISTURBANCES IN CONCENTRATIONS OF ELECTROLYTES

**Acidosis.** The preceding discussion has been devoted to therapy of clinical conditions in which the volume of body fluids is reduced with or without associated alterations in concentrations of electrolytes. In some instances acidosis may persist, particularly in infants recovering from diarrhea and in patients with renal insufficiency. The dosage of sodium lactate, acetate or bicarbonate necessary for the correction of this acidosis can be calculated from the following formula:

$$(C_d - C_a) \times f_a \times \text{body weight in kg.} = \text{mEq. required}$$

Here  $C_d$  and  $C_a$  represent respectively the concentration desired and the one actually present;  $f_a$  represents that fraction of the total body weight in which the administered material is apparently (not actually) distributed. This factor, of course, varies with the substance administered.

The apparent distribution factor for bicarbonate or potential bicarbonate is empirically determined and approximates one half to six tenths of the body weight. In terms of such a calculation, 4.2 ml. of sixth-molar sodium lactate solution or 0.058 gm. of sodium bicarbonate per kilogram of body weight would raise the serum bicarbonate concentration approximately 1 mEq. per liter. However, wide variations in individual response to administered bicarbonate occur, since administered sodium may be sequestered in bone or muscle or lost in urine. In glomerular insufficiency caution must be exercised in correcting acidosis; hyperphosphatemia should be corrected by diet and administration of aluminum hydroxide before the pH of the blood is elevated.

**Hypochloremic Alkalosis.** Rarely respiration may be so depressed in infants with severe hypochloremic alkalosis that oxygenation of the blood is diminished. Severe alkalotic tetany may also occur. In such instances the administration of ammonium chloride may effect symptomatic improvement. The dose of ammonium chloride may be calculated from the preceding formula; the probable  $f_a$  is 0.2 to 0.3. Such therapy is for relief of symptoms only and must not be used in place of administration of potassium chloride for repair of intracellular deficits.

**Hyponatremia.** Sodium chloride is the main solute of extracellular fluid. Hyponatremia, therefore, always indicates hypo-osmolarity except in the presence of hyperglycemia and hyperlipemia as in diabetic acidosis (p. 189).

A lowered concentration of sodium in the serum may result from a decrease in the amount of sodium in the extracellular space or from an increase in the volume of extracellular water (Table 38).

Of particular pediatric interest are the disturbances in sodium concentration related to diseases of the central nervous system. They seem to be of three types:

1. Patients with diverse lesions such as encephalitis, bulbar poliomyelitis, cerebrovascular accidents, tumors of the fourth ventricle and subdural hematoma may lose large amounts of sodium in the urine. These so-called cerebral salt wasters show signs of sodium depletion such as dehydration, hypotension and azotemia unless large amounts of salt are administered and the intake of water is somewhat limited.

Table 38. Clinical States Complicated by Hyponatremia

I. Expansion of extracellular space
A. Excessive intake
1. Parenteral fluid therapy—glucose in water
2. Oral (with diminished output)
B. Diminished output (usual intake)
1. Renal
a. Intrinsic: nephritis, nephrosis, tubular necrosis, prematurity
b. Extrinsic
(1) Excess of antidiuretic hormone—acute central nervous system disease, Pitressin therapy, surgery
(2) Circulatory—heart failure, cardiovascular surgery, malnutrition
2. Skin—premature in high humidity
II. Deficiency of extracellular sodium
A. Inadequate intake
1. Low salt diet
2. Parenteral therapy with glucose in water
B. Excessive losses
1. Gastrointestinal—vomiting, salivary, gastric, biliary, pancreatic drainage, diarrhea, resin therapy, enemas (especially megacolon)
2. Genitourinary
a. Intrinsic renal disease—chronic nephritis, acute tubular necrosis (recovery phase), nephrosis (diuresis)
b. Extrinsic influences—mercurial diuretics, Diamox, hypoadrenalism, central nervous system disease, pulmonary disease, expanded volume (Pitressin, excessive water therapy)
c. Arachnoid—ureterostomy
3. Skin
a. Normal sweat
b. Abnormal sweat—cystic fibrosis, adrenal insufficiency
4. Parenteral—thoracentesis, paracentesis, burns
C. Redistribution
1. Potassium deficiency
2. Trauma

2. Patients with tuberculous meningitis who are severely ill and comatose are frequently hyponatremic, but exhibit no symptoms which can be attributed to hyponatremia. This situation may be analogous to the asymptomatic hyponatremia of severe malnutrition or pulmonary disease. Relatively large amounts of salt may be lost in the urine when attempts are made to correct the hyponatremia by salt loading. It has been postulated that there may be a deficit of intracellular solute which leads to a homeostatic lowering of osmolarity. Careful clinical and laboratory observations are essential to ensure that salt depletion and water intoxication do not occur. Potassium should be administered in amounts at least 50 per cent greater than usual maintenance therapy (see p. 194).

3. Patients with acute infections of the central nervous system occasionally have symptoms of acute water intoxication as a manifestation of rapid fall in serum sodium concentration. These patients retain an excessive amount of water and have excessive thirst. Convulsions are severe and resistant to anticonvulsant therapy, but respond rapidly to the intravenous administration of hypertonic saline solution. The dose may be calculated according to the formula on page 191. Since there is osmotic equilibrium between cells and extracellular water, changes in osmolarity are distributed over total body water, and the value of 0.6 to 0.7 may be used for  $f_a$ .

Elevation of the sodium concentration should be effected in small increments (5 to 10 mEq. per liter) over one to four hours. A dose of 12 ml. per kilogram of body weight of 3 per cent (M/2) saline solution should raise the concentration of sodium approximately 10 mEq. per liter.\*

If no symptoms are present, correction of hyponatremia may be accomplished by restriction of water, administration of alcohol to produce a water diuresis or brief substitution of isotonic electrolyte solution for the usual water intake. In the therapy of disturbances in concentration, accurate chemical analyses are essential for confirmation of clinical findings. However, therapy must be directed at correction of symptoms and not at laboratory findings. Central nervous system diseases in which *hypernatremia* predominates must be differentiated; in these situations further limi-

tation of the intake of water would be disastrous.

**Hypopotassemia or Hypokalemia.** Disturbances in concentration of potassium in the absence of disturbances of volume of body fluids have been described in primary hypoadosteronism and in a poorly defined condition termed congenital alkalosis of renal origin. In these disturbances large amounts of potassium are lost in the urine, resulting in low serum potassium and high serum bicarbonate concentrations. The administration of large amounts of potassium (10 mEq. per kilogram per day) and severe restriction of the intake of sodium effect some clinical as well as biochemical improvement. Congenital alkalosis of gastrointestinal origin represents another anomaly of metabolism in which large amounts of potassium and chloride are lost in the stools (p. 189).

**Hypocalcemia and Hypercalcemia** are discussed on pages 1175 and 1177.

## MAINTENANCE THERAPY

This phase of fluid therapy is concerned with supplying the usual requirements of water, electrolytes, protein and calories. Such therapy, either by oral or parenteral routes, directly follows deficit therapy and is continued until the usual dietary intake is re-established. As noted previously, deficit therapy is calculated on the basis of body weight. Maintenance requirements, on the other hand, depend upon the rate of metabolic turnover and hence are calculated on the basis of 100 calories metabolized (Darrow and Pratt). The use of such a unit rather than surface area has a sound theoretic basis and does not unduly complicate practical therapy, since the pediatrician commonly thinks in terms of caloric requirements in infant feeding (see Table 37).

Use of ideal weight as obtained from the fiftieth percentile for age and height from the table on page 50 is necessary for obese infants and children. Calculation of the total number of calories metabolized is readily made by the additions or subtractions listed below in Table 39. Such corrections must be made to assure optimal intake rather than to depend upon estimations determined from a fixed surface area. Corrections for activity may be approximated by observation of the patient. No increments for activity are needed for patients in coma or under anesthesia. Usual bed activity does not exceed an increment

\*  $(10) \times 0.6 \times 1 = 6$  mEq. per kg. required.

1 ml. 3% NaCl = 0.5 mEq.

Therefore, 12 ml. per kg. required.

20 to 30 per cent. In the first three to five days of life, activity is low and total caloric expenditure does not usually exceed 50 calories per kilogram of body weight. Increments for growth may be ignored, as may those for specific dynamic action, unless large amounts of amino acids or alcohol are administered.

The range as well as the usual losses of water and electrolytes from the lungs and skin, in the stool and in the urine is charted in Table 40 per 100 calories metabolized. The amount of water necessary for urine formation is directly related to the concentrating or diluting activities of the kidney and

to the renal solute load, which is largely a function of the diet (Fig. 35). The approximate solute excretion for patients receiving no electrolyte and adequate carbohydrate to minimize tissue breakdown is 10 to 15 milliosmols per 100 calories metabolized. Usual electrolyte allowances would increase this value to 20 to 25 milliosmols per 100 calories. The amount of exogenous water needed to meet maintenance needs is approximately 10 to 15 ml. per 100 calories less than total requirements because of the release of that volume of water during oxidation of endogenous and exogenous carbohydrate, fat and protein. Thus the maintenance supply of water for the average patient ranges from 110 to 120 ml. per 100 calories metabolized. Such an allowance permits excretion of solutes without maximal dilution or concentration of the urine. This volume of fluid is less than that prescribed in usual oral infant feeding (140 ml. per 100 calories of food) because the intake of excretable solute is considerably greater on a milk or other protein-containing diet.

With alterations in body functions, adjustments in water allowances for maintenance must be made. In anuria or extreme oliguria (less than 10 ml. per 100 calories metabolized) only about 45 ml. of exogenous

FIG. 35. Relationship of water requirement for urine formation to urinary concentration and dietary renal solute load. (Modified slightly from Darrow and Pratt, J.A.M.A., Vol. 143.)

water per 100 calories are required, since only evaporative and stool losses occur. Careful calculation of water of oxidation is particularly important in this condition, and water allowances should be adjusted accordingly. In the presence of excessive release of antidiuretic hormone as in some acute infections, particularly of the central nervous system, the intake should not exceed 80 to 90 ml. per 100 calories. When urinary specific gravity is fixed as in chronic renal disease, water requirements rise to 140 ml. per 100 calories, and in diabetes insipidus of nephrogenic or hypothalamic origin to as high as 400 ml. per 100 calories. In such instances the thirst of the patient and an awareness of the urinary output are usually more reliable than the physician's estimates, and oral feedings should be used if possible; urinary losses of water must not be replaced on a volume-for-volume basis. The author has observed adult patients who put out daily volumes of urine up to 8 and 10 liters in order to excrete loads of water administered "to balance" urinary losses incident to an initial diuresis of fluid retained during an oliguric phase. In hyperventilation and in heat stress evaporative losses of water may increase as much as 90 and 120 ml. per 100 calories, respectively, and increments in fluid intake should be made accordingly. High humidity environments, such as in incubators, may reduce evaporative losses of water by 20 to 50 per cent, and appropriate decrements in intake should be made.

Although there is great variability in excretion of electrolytes (Table 40), the sodium and potassium requirements for the average patient receiving parenteral fluids are 2 to 4 and 2 to 3 mEq., respectively, per 100 calories metabolized. A solution of 5 or 10 per cent invert sugar containing 30 mEq. per liter of sodium and chloride and 20 mEq. per liter of potassium as the lactate, acetate or glutamate salt represents an adequate maintenance solution\* which meets the usual requirements when given in amounts of 110 to 120 ml. per 100 calories metabolized. Such a solution should be given *only* intravenously at a fairly constant rate throughout

* 5 or 10% invert sugar or glucose in

the day. If maintenance therapy must be conducted by subcutaneous administration of fluid, owing to technical difficulties, equal parts of 5 per cent glucose or 5 per cent invert sugar in water and Darrow's K lactate may be administered. Glucose in water or a very dilute electrolyte solution should not be given, since diffusion of sodium chloride and water into such an extravascular pool may acutely reduce plasma volume and precipitate shock.

Just as intake of water must be adjusted to meet specific alterations in body functions, so must intakes of electrolytes be individualized. For example, in anuria or oliguria no electrolyte should be administered for maintenance. In congestive heart failure limitation of sodium intake is as important in parenteral as in oral therapy. Reduction of sodium intake during fluid therapy of a patient with cardiac failure also demands some limitation of water since renal solute load is decreased and retention of water may occur.

In parenteral maintenance therapy for extended periods of time, and particularly in malnourished patients, carbohydrate, alcohol and amino acids may be necessary to attain caloric and nitrogen balance. A solution containing 10 per cent fructose, 2.5 per cent alcohol and 2.5 per cent Amigen,† plus necessary electrolytes for maintenance, has been used successfully by the author for complete parenteral alimentation. Albumin may be given as a source of preformed protein intravenously in doses of 3 gm. per 100 calories metabolized, particularly when severe malnutrition is present. The addition of a multivitamin preparation such as Berocca is indicated whenever previous nutrition was poor and maintenance therapy is prolonged.

Regardless of the accuracy of planning, periodic analyses of the serum and frequent physical examinations of the patient must be carried out in order to assess alterations in concentration and volume of body fluids as therapy progresses. Measurements of the non-protein nitrogen or blood urea nitrogen and the serum sodium, chloride and potassium levels are essential at intervals of twenty-four to seventy-two hours, depending on the clinical status of the patient. Such analyses may now be performed in many laboratories of capillary blood.

† Supplied by Mead Johnson & Co. Now available commercially as 5% Amigen, 12.5% Levogen and 2.5% alcohol.

MAINTENANCE THERAPY IN PREOPERATIVE, PARAOPERATIVE AND POSTOPERATIVE CARE

Preoperative preparation of a patient who has no pre-existing deficit or in whom the deficit has been repaired consists mainly in the supply of carbohydrate to ensure adequate storage of glycogen in the liver. The requirements of water and electrolytes for maintenance are similar to those for the average patient. As for small infants who are not vomiting, carbohydrate and sodium chloride mixtures should be given by mouth until three hours before operation. Such fluids are readily absorbed from the gastrointestinal tract and will not produce aspiration pneumonitis if vomited. During operation and for the first twenty-four hours postoperatively, limitation of water and electrolytes is indicated. Owing to the dangers of anoxia and shock, no potassium should be administered during these periods. The water intake should not exceed 35 ml. per 100 calories metabolized because of antidiuresis resulting from trauma or circulatory readjustment unless renal insufficiency and limited concentrating capacity are present. If the intake of water is not limited, whether given parenterally or by mouth, water intoxication may result. Sodium intake should also be low, owing to the low caloric expenditure during anesthesia and postoperatively. During operation, fluid, such as blood or plasma, must be given to meet large losses into traumatized tissue. The magnitude of such internal abnormal losses is judged best by the experienced surgeon as he operates. Postoperatively, limitation of intake should be maintained for twenty-four hours. Thereafter, usual maintenance therapy is gradually resumed.

ABNORMAL LOSSES OF WATER AND ELECTROLYTES

The principles underlying the concomitant replacement of external abnormal losses require little explanation. Such losses depend on the specific clinical disturbance (see Table 41) and must be replaced as they occur in order to prevent the development of further deficits. Considerable variation in composition exists from patient to patient and from time to time in the same patient. Although only an approximation can be made, these losses must be replaced, as nearly as possible, volume for volume as they occur in order to prevent physiologic readjustments which may further deplete the body of water

and electrolyte. Gastric or intestinal drainage can be replaced satisfactorily by solutions which are isotonic or somewhat hypotonic and contain some excess of chloride over sodium for gastric replacement and sodium over chloride for intestinal replacement. Ten to 20 mEq. of potassium should also be included. Losses of sodium chloride in sweat are of little significance except in adrenal insufficiency and cystic fibrosis of the pancreas. Heat stress should be avoided in such patients.

**Burns.** Internal abnormal losses of fluids are difficult to quantitate. This phase of fluid therapy is exemplified by the treatment of burns. Unless unusual delay has occurred before a burned child is brought to the hospital, pre-existing deficits are minimal and significant deficits result solely from inadequate or delayed fluid therapy after admission. Maintenance requirements for water are diminished when the large surface area is covered by wet dressings which limit evaporation from the skin; evaporation from the lungs is normal or increased. Urinary output of water is probably limited by some antidiuresis which results from massive stimulation of nerve receptors. Thus the fluid therapy of burns is concerned principally with the replacement of abnormal losses. Some of these losses are external, such as plasma oozing from the burned surface. In addition, a significant number of erythrocytes are destroyed or damaged by exposure to heat, and their survival time is shortened. The largest part of the abnormal loss is internal in the form of plasma and plasma ultrafiltrate sequestered around the burn site. The magnitude of this sequestration has been approximated by measurements of the extracellular space in patients with severe burns. Such measurements are partially invalidated, however, by the fact that

Table 41. Composition of External Abnormal Losses

large amounts of saline solution were administered therapeutically, and true obligatory losses can only be approximated.

Losses of fluids are proportional not to the weight or metabolism of the patient, but to the surface area of the second- or third-degree burn. This area can be approximated by the "rule of nine"\* or from appropriate charts of the body surface.

The composition of an ideal replacement solution cannot be fixed. A mixture of 3 parts of plasma, 1 part of blood and 3 parts of a balanced saline solution† represents a reasonable replacement fluid which may be given at the rate of 10 liters per square meter of second- or third-degree burned surface area per forty-eight hours. A third is administered in the first six hours, a third in the next twelve hours and a third in the next thirty hours. Such a program can only approximate the actual needs. The progress of therapy must be monitored at one- to two-hour intervals by the determination of hematocrits of capillary blood and of plasma protein levels and by careful measurements of the volume and concentration of urine obtained by an indwelling catheter. Urine volume should remain at 30 to 50 ml. per 100 calories metabolized. A rising hematocrit value and falling urine volume, for example, indicate an inadequate rate of replacement of fluids. After forty-eight hours fluid therapy should be sharply limited. The sequestered fluid may return at this time to the vascular compartment and produce acute pulmonary edema, particularly if there has been thermal injury to the lungs. Digitalis and mercurial diuretics, if there has been no renal injury, may be helpful at this time.

**Abnormal Urinary Losses.** There are certain conditions in which occult abnormal losses occur into the urine. Sodium-losing disorders such as pulmonary, cerebral or adrenal "salt wasting" or potassium-losing disorders such as primary hyperaldosteronism or congenital alkalosis of renal origin may be suspected when there are alterations in con-

centrations of serum electrolytes in the absence of obvious losses. "Wasting" a particular electrolyte is established when excessive quantities of it are demonstrated in the urine in the presence of restricted intake and a low serum concentration in association with normal or reduced volume of body fluid. "Spot tests" which indicate only the concentration of electrolytes in the urine are inadequate for diagnostic purposes.

## SUPPLEMENTAL THERAPY

It is occasionally necessary in fluid therapy to supply an excess of certain substances to effect a particular change in physiological function or to facilitate excretion of a particular substance. Such therapy in the form of water and electrolytes is given in the absence of specific deficits and above the usual needs.

**Salicylate Poisoning.** Supplemental therapy is of particular importance in the treatment of salicylate poisoning. The initial effect of a high concentration of salicylate is to sensitize the respiratory center to carbon dioxide. The resultant hyperventilation leads to increased evaporative losses of water and to respiratory alkalosis. The renal compensation for respiratory alkalosis consists in the excretion of large amounts of sodium and potassium bicarbonate. In addition, to levels of salicylate may reduce hepatic glycogen. Ketonemia and ketonuria usually result, and occasionally there is hypoglycemia. The loss of sodium and potassium in excess of chloride and the accumulation of acetoacetic and beta-hydroxybutyric acids eventually lead to severe metabolic acidosis. Transition from respiratory alkalosis to metabolic acidosis may be relatively rapid. Therapy must be followed by periodic evaluation of the serum carbon dioxide content and the pH of blood and urine. Early in therapy adequate amounts of water, carbohydrate and electrolytes must be supplied to meet the increased evaporative losses and to permit maximal renal compensation. Approximately 160 to 180 ml. of water, 15 gm. of invert sugar or glucose, 6 to 8 mEq. of sodium and 3 to 6 mEq. of potassium per 100 calories metabolized should be given.

As the phase of metabolic acidosis begins, administration of sodium bicarbonate or potassium acetate or glutamate to maintain alkaline urine (pH >7.5) will facilitate excretion of salicylate. The dose of bicarbonate necessary to alkalinize the urine is

\* Head, arm, one quarter of trunk, one half of leg: each equals 9 per cent of the body surface. The sum of the percentages times total surface area as given by nomogram on page 209 equals the area used in calculating requirements. Infants and small children, owing to relatively larger heads and trunks and smaller extremities, fit more exactly to a "rule of sixes." Arm, one half of head or leg and one eighth of trunk: each equals 6 per cent of the body surface.

proximately 5 mEq. per kilogram of body weight, which can be given over twelve hours in divided doses. Approximately 2 of the 5 mEq. of cation should be given as potassium to prevent alkalosis and to avoid renal tubular potassium depletion with paradoxical aciduria. Exchange transfusion or dialysis by means of the artificial kidney may also be used to remove salicylate loosely bound to plasma proteins in severely ill patients with high blood levels of salicylate.

**Potassium Intoxication.** The excretion of potassium may be increased acutely by loading with hypertonic sodium bicarbonate (2 mEq. per kilogram in one hour as M/2 sodium bicarbonate). Such supplemental therapy may be lifesaving in acute hyperkalemia, since elevation of serum sodium concentration and pH reduces serum potassium concentration even in the nephrectomized animal. A small amount of invert sugar and 0.2 unit of insulin per kilogram may accelerate the shift of potassium from the extracellular to the intracellular space.

Although water loading may be considered a form of supplemental therapy, excretion of solute, such as urea in glomerular insufficiency, is not increased by such a procedure unless pre-existing dehydration is present. Water retention, edema or water intoxication may result.

## PARENTERAL SOLUTIONS

Table 42 lists various solutions commercially available for use in deficit, maintenance, abnormal loss replacement and supplemental therapy. The large number of carbohydrate and electrolyte mixtures available permits great flexibility and individualization of therapy.

## ADMINISTRATION OF PARENTERAL FLUIDS

Parenteral fluid therapy is dependent not only upon the correct choice of fluids, but also upon the ability of the physician to administer these fluids adequately. This requires the development of technical skill, particu-

larly in intravenous administrations, since this is the preferred route for most solutions and the required one for some.

Other routes for the parenteral administration of fluids are the subcutaneous, periton-

and intraosseous ones. The subcutaneous route has limitations which are also applicable to intraperitoneal administrations. The peritoneal and intraosseous routes are dangerous because of the possibility of infection; their use is not recommended except in extraordinary circumstances. In patients in profound shock, the prompt use of the intraosseous space for blood transfusion may occasionally be lifesaving.

### INTRAVENOUS INFUSIONS

**Long-Term Intravenous Infusion.** Success in intravenous therapy which extends for a day or more depends upon proper restraint of the patient, adequate and well prepared equipment and skill in cannulating the vein.

In infants and young children the veins about the wrists and feet offer the best sites for intravenous administrations. The lower arm and hand or the lower leg and foot are more easily immobilized than the upper portions of the extremities, and the veins will generally receive 22- or 23-gauge needles without difficulty. Larger needles can often be used, and, in general, the largest needle which will fit the vein will be the easiest to use. Immobilization is best obtained by fastening the hand and lower arm or foot and lower leg with wide adhesive ( $\frac{3}{4}$  inch) to a well packed sandbag of appropriate shape and of sufficient weight to maintain the extremity in a satisfactory position. In older children the veins in the antecubital area may be used, but adequate restraint is difficult to obtain except in a cooperative child.

Veins of the scalp are sometimes easy to cannulate in infants, but it is difficult to immobilize the head, so that these veins do not lend themselves to continuous infusions unless the need for restraint is lessened, as it may be through the use of the Gardner and Murphy needle. This consists of a needle shaft without a hub, to which is attached 6 to 8 inches of polyethylene tubing, thus permitting the bulky stopcock and syringe to be placed at a position not immediately adjacent to the head.

In exceptional circumstances when an assured route of fluid administration is urgently needed, as during surgical procedures, it is expedient to "cut down" on the saphenous vein at the ankle and cannulate the vein with a nonwetttable plastic tubing which will not be so easily dislodged from the vein as a needle.

**Venipuncture.** A satisfactory system for the administration of intravenous fluids con-

sists of a closed fluid container,\* disposable plastic tubing with a drip chamber and with blood or plasma filters when needed, terminating in a three-way stopcock to which the needle and a 10- or 20-ml. syringe are attached. The needle should be the largest which can be used for the vein chosen; a flat bevel about twice as long as the thickness of the needle is satisfactory. The needle should be carefully examined for irregularities of the cutting edge and for patency. A few milliliters of saline solution are then drawn into the syringe, and any air present is evacuated.

With the extremity carefully immobilized, the skin over the vein is prepared with alcohol or Zephiran solution and the vein distended by pressure over its proximal portion. The needle is inserted through the skin directly above the vein and, with the bevel up, is advanced through the tissues parallel to and above the vein in such a way that the bevelled edge carries it into the vein. The point at which this occurs can often be seen. If penetration of the vein is not seen but suspected, it may be confirmed by the appearance of blood in the syringe or by the fact that saline solution may be easily pushed into the vein without the formation of a nodule of extravasation about the point of the needle.

When the needle enters the vein, it may be expedient to advance it cautiously while saline solution is injected to keep the vein dilated before the advancing edge of the needle. The needle is then taped securely to the skin and the stopcock turned to permit flow of fluid through the drip chamber at the desired rate. If it is intended to give the fluid requirement for twenty-four hours, the rate of flow will vary from about 0.5 to 1 ml. per minute, depending upon the size of the patient and the clinical problem.

**Cannulation of a vein.** The internal malleolar vein is usually chosen for insertion of plastic tubing or a cannula. Initially the vein is located just above the internal malleolus by application of a tourniquet, and the area is prepared by sterilization of the skin and establishment of local anesthesia. An incision is then made transversely through the skin over the vein, and the vein is brought into view by blunt dissection. A suture is passed behind the vein and tied as far distally as possible. A small transverse incision is then

\* Commercial preparations of standard solutions, available in sealed bottles, are provided with sterile packets of dispensable plastic tubing and with air filters. The use of such equipment eliminates some of the factors which contribute to contamination.

made in the vein, and a polyethylene or other suitable plastic catheter of proper size is inserted for a distance of a few centimeters. A second suture is tied over the tubing proximal to its point of entry into the vein. The incision in the skin may then be closed with a suture or two. Catheters so placed may be used for several days. The catheter may be kept open when no fluid is actually going through by filling it with saline solution containing a little heparin to retard or prevent clotting at the end of the tubing. If signs of infection or phlebitis occur, the tubing should be promptly removed.

**Short-Term Intravenous Infusion.** When intravenous therapy is limited to a small amount of fluid for a relatively short time, as for an elective blood transfusion, operative cannulation of veins is not recommended unless absolutely necessary, since the vein will not subsequently be available for intravenous therapy and since disfiguring scars sometimes result. The technique for infusion by venipuncture is applicable here. In infants the veins of the scalp may be used effectively if an assistant is available to hold the head for the duration of the procedure. The infant is restrained in a blanket and his head held at the edge of a table, where the operator may carry out the transfusion through manipulation of the stopcock and syringe, taking care not to allow movement of the needle once entry into the vein is made. The rate of infusion should not ordinarily exceed 10 ml. per minute, and in the case of cardiac failure or other serious disturbance may need to be much less (1 to 5 ml. per minute).

### SUBCUTANEOUS INFUSIONS

Subcutaneous fluid administration is limited to solutions of electrolytes of approximately isotonic strength. Solutions of glucose in water are unsuitable because they cause local irritation and may create movement of electrolytes into tissue spaces which defeats the aim of their administration. However, 2.5 per cent glucose in half-isotonic saline solution is well tolerated and is widely used. Solutions with less than this concentration of salt should not be used.

Fluid may be given under the skin on the lateral aspect of the thighs, in the axilla or, preferably, over the back of the trunk. The skin is prepared as for a venipuncture, a loose fold is picked up between the fingers, and the needle is pushed through at the base of the fold parallel to the underlying muscles to avoid penetration of them.

Prolonged subcutaneous infusions are usually given in the tissues of the anterior thigh with the patient restrained in the supine position. Infusions may be given into each thigh simultaneously with a Y adapter through 20-gauge needles, 2 or 3 inches in length. The needles must be securely anchored with adhesive tape. When the infusion is finished, the needle holes should be sealed with collodion.

In infants, when only a small amount of fluid is needed (not more than 40 ml. per kilogram), subcutaneous infusions may be given by syringe into tissues of the back. A long needle is inserted below the tip of the scapula and directed upwards into the interscapular and lateral areas of the back. Fluid is injected during the advance of the needle not exceeding in any position an amount which causes blanching of the skin over the tip of the needle. The needle is then almost completely withdrawn before being redirected in a like manner, so that trauma from redirection of the needle is kept at a minimum.

### INTRAMEDULLARY INFUSIONS

Owing to the danger of infection, the use of intraosseous infusions is limited mainly to emergency administration of blood plasma or other fluids in severe shock when there is collapse of peripheral veins. The sternal marrow may be used in children over five or six years of age, and the tibial and femoral marrows in younger children and infants. Special needles with stilets are recommended. The need for asepsis is of utmost importance. Care should be taken in performing the sternal puncture not to penetrate the mediastinum. The upper third of the tibia and the lower third of the femur are the sites chosen; the needle should be directed away from the epiphysis. The use of marrow infusions is contraindicated in septicemia and when it is necessary to introduce the needle through infected skin.

### BLOOD TRANSFUSION

Transfusion of whole blood or of products derived from whole blood may be specifically required in treatment of shock, in replacement of losses due to injury or surgical procedures, and in various hematologic disorders. Transfusion may be used less specifically as a supportive measure in many disturbances in infants and children. Adequate indications for transfusion of blood or blood derivatives should always be insisted upon, since blood transfusion is an expensive and often potentially harmful form of therapy.

Whole blood is most commonly used in transfusion, but often some fraction of whole blood or plasma will supply the patient's needs. For example, sedimented red blood cells may be preferred in the treatment of anemia; preparations rich in platelets, for the treatment of thrombocytopenia. "Platelet preparations" require silicone-coated glass or nonwetable plastic surfaces for collection and administration. Plasma or plasma derivatives may be preferable for certain hemorrhagic disorders or hypoproteinemias.

The safety of blood transfusions must be assured (1) by prevention of immediate reactions in the recipient resulting from antibodies ("natural" or acquired by prior transfusion) against the transfused cells, and (2) by prevention of formation of antibodies in the recipient, which might jeopardize future transfusions or cause hemolytic disease of the newborn in an offspring of a female recipient. The Rh (D or Rh<sub>o</sub>) antigens are the major untoward factors. Accurate typing of donor and recipient with respect to the A-B-O and Rh (D or Rh<sub>o</sub>) antigens and adequate cross-matching of the two bloods provide the necessary assurance.

The *cross-match*, which suspends donor's cells in recipient's serum (major cross-match) and recipient's cells in donor's serum (minor cross-match) determines (1) whether the recipient's blood contains antibody for donor's cells ("major mismatch") and (2) whether the transfused blood contains an antibody for the patient's cells ("minor mismatch"). The major mismatch is more dangerous than the minor, since the recipient has relatively large stores of antibody, whereas donor antibody is usually diluted in the recipient to an innocuous level.

A blood transfusion ought not to be given without cross-matching except in the most acute emergency; at such times group O blood which is Rh (D or Rh<sub>o</sub>) negative is probably safest. The use of group O blood, which contains anti-A and anti-B factors, as "universal donor" blood for A, B or AB recipients should be avoided if at all possible. When there is no alternative, blood should be chosen, if possible, which has low titers of anti-A and anti-B and in which the anti-A and anti-B are not hemolytic or resistant to neutralization by A and B specific polysaccharide substances. The addition of the latter substances to group O blood probably does not greatly reduce any potential danger from minor mismatch incompatibilities.

There are variations in the techniques of the cross-match, but certain factors appear to be basic. First, since antibodies formed in response to sensitizing transfusions are usually not active in a suspending medium of isotonic saline solution, the cross-match should be set up in the native serums of the donor and recipient, or in such mediums as 20 per cent bovine albumin or albumin-serum mixtures. If cells must be suspended in saline solution, their agglutinability may be enhanced by partial digestion by such enzymes as trypsin or papain. In recipients who have had previous transfusions all these techniques may fail to detect certain antibodies, notably anti-Kell and anti-Duffy, so that it is essential that the cross-matching procedure should demonstrate compatibility on the major side, at least, by the indirect antiglobulin technique (Coombs' test).\*

\* A positive antiglobulin reaction occurs when red blood cells become coated with specific antibody. The coating globulin antibodies often fail to cause agglutination of the coated cells in certain mediums. In such instances the globulin antibody may be detected indirectly through the phenomenon of precipitation with an antiglobulin serum.

Antiglobulin serum for the test is prepared in rabbits by injection of human serum. The rabbit forms antiglobulin precipitins which may be assayed by precipitin titration against normal serum. Animal serums so prepared are absorbed with human cells of various types to remove all species-specific cellular agglutinins. The serum precipitins remain.

The indirect antiglobulin test is carried out as follows: 2 drops of 2 to 5 per cent suspension of red blood cells in saline solution are added to 2 drops of the serum suspected of having antibodies for the chosen cells. After incubation for fifteen minutes at 37° C. the cells are washed three times in saline solution and reconstituted to a 2 per cent suspension. A drop or two of potent antiglobulin reagent is added, and the suspension is centrifuged at low speed for a minute. The tube is then lightly shaken; if agglutination is present, it indicates that the cells have been coated with antibody of the serum to which the cells were exposed. The observed agglutination is the by-product of the precipitation of globulin particles on adjacent cells.

In erythroblastosis fetalis and certain acquired hemolytic anemias the red blood cells of the patient may institute an immediate positive antiglobulin reaction after washing (*direct* antiglobulin reaction, or Coombs' test). In erythroblastosis fetalis the antibodies are transferred to the fetus through the placenta; in acquired hemolytic anemia auto-antibodies may be formed in the patient as part of the morbid process.

The antiglobulin reaction is the most sensitive method for detection of coating antibody, but it does not indicate the specificity of the coating particles. This identity must be established by studying the reactions of a number of cells of known types.

The possibility that a blood transfusion will sensitize the recipient and thus create the potential for future untoward transfusion reactions will practically be eliminated by avoiding the transfusion of Rh<sub>0</sub> (D)-positive blood to an Rh<sub>0</sub> (D)-negative recipient. Routine screening for less common incompatibilities is impractical. Rh<sub>0</sub> (D)-negative blood should be chosen for the Rh<sub>0</sub>-negative recipient so as to exclude the weakly reactive bloods known collectively as D<sup>u</sup> positive; such blood may be strongly antigenic in Rh<sub>0</sub>-negative persons. The safest method of exclusion at present is to test by the indirect antiglobulin technique (Coombs' test) all donor bloods which appears to be Rh<sub>0</sub> negative. Blood which has a positive reaction with anti-Rh<sub>0</sub> (anti-D) serum by this technique should be considered D<sup>u</sup> positive and be given only to Rh<sub>0</sub>-positive recipients.

Other reactions which may complicate transfusions include (1) febrile responses to pyrogens, (2) allergic reactions to ingested allergens or to reagins in the blood of the donor or to other factors in the plasma of the donor to which the recipient is sensitive, (3) severe toxic reactions caused by bacterial contamination of donor blood during collection or storage, (4) homologous serum hepatitis, (5) rarely, a toxic reaction to an elevated potassium level of the donor blood which normally occurs during storage.

Pyrogenic reactions are most often the result of improper cleansing of tubing and needles. Such reactions can be avoided or minimized by scrupulous cleanliness of equipment or by use of properly prepared disposable tubing for all intravenous therapy.

Allergic reactions can be avoided by delaying withdrawal of blood from the donor until after a suitable fasting interval and by rejection of allergic persons as donors. Reactions to plasma proteins occur most often in recipients of multiple transfusions, who may have febrile and urticarial responses regardless of how carefully the donor may be chosen. If the need is principally for red blood cells, sedimented cells may be given in place of whole blood to minimize the allergic response. Administration of aspirin and an antihista-

minic drug before and during transfusion provides additional precautions.

The severity of the toxic reaction to blood contaminated with bacteria necessitates the utmost care in the collection, storage and use of blood. Blood should remain in the bank until time for its use and should not be used if exposed to room temperature for more than a few hours.

Homologous serum hepatitis is less likely to occur after blood transfusion than after the administration of pooled plasma or plasma products. Its occurrence, however, is a strong argument against the unnecessary use of blood transfusions and against the choice of donors who have had jaundice.

Toxic reactions to elevated serum potassium levels in donor blood are most likely when large amounts of blood are used, as in exchange transfusions. Blood for this procedure should, under optimal conditions, be freshly drawn, and should in no instance be stored longer than four days. If a reaction is suspected during the course of an exchange transfusion, prompt administration of 5 to 10 ml. of 10 per cent calcium gluconate solution may prove lifesaving.

The amount of blood given in a transfusion should vary according to the clinical problem: the need during active hemorrhage may be for continuous transfusion; in an anemic newborn infant, for a relatively small transfusion of sedimented cells. Except for continuing hemorrhage or shock, transfusion should not exceed 10 ml. per pound (20 ml. per kilogram) of body weight if whole blood is used, or 5 to 7 ml. per pound (10 to 15 ml. per kilogram) if sedimented cells are used. Somewhat larger amounts of blood may be used if administered very slowly by intravenous drip, but the possibility of precipitation of cardiac failure and pulmonary congestion by intolerable increases in blood volume or viscosity should be guarded against. In such patients an *exchange transfusion* may permit efficient restoration of the oxygen-carrying capacity of the blood without changing, or with a salutary decrease in, blood volume.

VICTOR C. VAUGHAN, D

## TECHNICAL PROCEDURES

### COLLECTION OF SPECIMENS

**Urine.** The collection of urine specimens in infants and children who have not acquired voluntary sphincter control requires special techniques. In boys a smooth-glass test tube may be fastened over the penis with a 2- or 3-inch square of adhesive tape. The tube is slipped through a hole in the middle of the tape and made watertight with a band of adhesive. The square is then folded to the perineum. In girls a feeding cup from a bird cage may be substituted for the test tube, or a soft polyethylene diaper, which contains a reservoir for collection of urine, may be used.

Twenty-four hour specimens may be obtained from boys by securely fastening a soft rubber tube (Penrose tubing) or plastic tubing about the penis so as to make it watertight over the perineum and placing the open end in a collecting bottle. In girls plastic tubing may be taped to the vulva or fixed with skin cement. A metabolism bed is more effective.

If a specimen is urgently needed, catheterization may be performed. A small silk catheter, no. 9 or 10 French scale or no. 4 American scale, can usually be passed without difficulty. Utmost care should be used to avoid trauma and the introduction of infection. Catheterization should be used routinely only to secure urine for bacterial culture, to rule out external contamination in suspected pyuria in females, or to secure residual urine after voiding.

**Blood. Capillary blood.** Amounts up to 0.5 ml. of blood can often be obtained from finger or heel puncture. After preparation of the skin with alcohol solution or Zephiran, a stab is made, preferably on the *side* of the finger or heel, with a sharp, sterile (auto-sterilized) lancet. Only *disposable* lancets should be used, to avoid transmission of homologous serum hepatitis. For chemical determinations free flow of blood should be obtained, and milking or squeezing of the finger or heel should be avoided; otherwise, admixtures of tissue fluids may occur which vitiate the findings. After the puncture has been made and a free flow of blood obtained, the area should be wiped absolutely dry of any remaining sterilizing solution so that subsequent spreading of the blood due to reduction of surface tension is minimized.

**Venous blood.** In older children the veins

in the antecubital space are the most satisfactory for venipuncture. An uncooperative child may be held in the lap of an assistant, who holds the arm hyperextended while a tourniquet is lightly applied above the elbow. With the vein fixed in the tissues by hyperextension of the arm, the needle is inserted. If the vein appears to be readily available, penetration of the skin and vein may be made in one smooth motion. The most common errors are inadequate fixation, incomplete extension of the arm and improper direction of the needle toward the vein at an angle. The introduction and insertion of the needle should be in a plane nearly parallel to that of the vein.

In infants and young children blood is most readily obtained from the femoral and external jugular veins. Sometimes the scalp veins or those on the dorsum of the hand can be used. Rarely it may be necessary to use the internal jugular vein.

Use of the femoral vein requires an assistant to hold the leg flexed on the thigh with the knee maximally rotated outward and the thigh about half-abducted at the hip joint. The opposite leg may be put into a similar position and held there by the body of the assistant, who leans across an examining table to restrain the leg to be used. A 20- or 21-gauge needle with a 30-degree flat bevel should be used. The vein will be found just medial to the arterial pulsation, which can ordinarily be felt without difficulty at the inguinal crease. The needle is inserted through the skin about 1 inch below the inguinal crease and directed slightly cephalad to a position just medial to the artery under the guidance of the forefinger, which is kept on the pulsating artery. The vein is often transfixed, in which case the needle will usually strike the femur. Withdrawal of the needle for a short distance while slight negative pressure is maintained within the syringe will usually result in a spurt of blood into the syringe. When the specimen is obtained and the needle withdrawn, firm pressure over the vein should be maintained for a minute. If an artery is inadvertently entered, pressure should be continued longer. The cyanosis and mottling of the extremity which often accompany arterial puncture are usually transient.

For withdrawal of blood from the external jugular vein, the infant is wrapped securely

in a blanket and the supine body is steadied between the arms of the assistant, who holds the head extended and rotated between her hands over the side of the table opposite her. The external jugular vein is evident over the sternocleidomastoid muscle, and the needle may be inserted when the vein is distended by the crying of the infant.

The child must also be restrained in the foregoing manner for puncture of the internal jugular vein. A needle,  $1\frac{1}{2}$  inches in length, is inserted lateral to the sternocleidomastoid muscle at the junction of its upper and middle thirds, and advanced toward the tip of the index finger, which is placed in the supra-sternal notch. The vein is reached within  $\frac{1}{2}$  to  $\frac{3}{4}$  inch from the skin surface; if negative pressure is maintained in the syringe, entry into the vein will result in flow of blood into the syringe. Care should be taken to avoid the trachea and the pleura. This procedure should not be done unless the trachea is in the midline. When the needle is withdrawn from either the external or the internal jugular vein, the child should be put immediately in an upright position and pressure should be applied over the vein for a minute with a gauze sponge.

**Material for Bacterial Cultures from the Nasopharynx and Throat.** In bacterial pneumonias the pathogen can be isolated from the nasopharynx in a great many instances. A satisfactory swab can be prepared by attaching cotton with collodion to the end of a thin copper wire, which can then be autoclaved. With the child restrained, the tip of the nose is elevated with the thumb of one hand and the swab passed with the other hand into the nostril, along the floor of the nasal cavity close to the septum into the nasopharynx. The sensitive turbinates should be avoided unless a *nasal* swab is desired for culture or examination of a stained smear for eosinophils.

Material for a throat culture is obtained by swabbing the infected areas while the child is restrained and the tongue depressed. The exudate on the swabs *must* be streaked on appropriate mediums immediately, since it dries rapidly and pathogens may quickly become nonviable.

#### GAVAGE AND GASTRIC LAVAGE

**Gavage.** Feeding by stomach tube is indi-

cated for small premature infants who have inadequate sucking or swallowing function, and for infants and older children whose ability to swallow or retain nourishment is impaired.

In premature infants a small rubber catheter or small-bore polyethylene or other plastic tubing may be used, the latter having the advantage that it may be left in the stomach for several feedings. Polyethylene tubing for this purpose is available with a rounded tip to minimize danger of injury to the infant's tissues. It is not advisable to leave the tubing in place for more than a day or two because of the possibility of esophageal or gastric erosion. In older infants or children catheter or stomach tubes may be used. Here, too, there will be circumstances in which the use of continuous gavage by polyethylene or other plastic tubing will be advantageous.

Tubes for gavage should be moistened and passed with care through the nose or mouth and advanced slowly into the esophagus and stomach. If choking, coughing or aphonia suggests that the tubing may have entered the respiratory passages, it should be removed and reinserted. When the tube has been introduced a distance equal to that from the xiphoid to the nose, the tip will probably be in the stomach. Its position can be tested by introducing a few bubbles of air while auscultation is made over the left upper quadrant. Fluid given by gavage is best administered by gravity from an open container. The tube should be pinched off as it is removed to prevent leakage into the pharynx or respiratory tract.

**Gastric Lavage.** This procedure is used to remove stomach contents in instances of pyloric or high intestinal obstruction, delayed emptying, poisoning, and the like, or to obtain swallowed material of pulmonary origin for examination. The tube, which should be the largest practicable, should be passed in the manner described for gavage. Lavage may be accomplished by gravity, with the reservoir alternately raised and lowered to fill and siphon out the stomach contents, or more actively by the use of a syringe. A variety of washing solutions such as water, saline, bicarbonate solution and oils are used according to the clinical problem.

VICTOR C. VAUGHAN, M.D.

# DRUG THERAPY

## GENERAL CONSIDERATIONS

ational drug therapy is based on a clear understanding of the metabolic processes peculiar to the growing child, of the ways in which various diseases alter these processes, and of the mechanisms by which drugs may be remedial. Some medicinal therapy is still based on empirical knowledge, however, and such knowledge is essential to the practicing physician.

The success of therapy depends both on the adequacy of the treatment and on the method by which the treatment is administered. Owing to a lack of interest by physicians in supervising or even observing the administration of drugs, the actual benefit from many potentially useful agents may be lost. The administration of drugs to infants and toddlers is fraught with many problems. The task is not fulfilled when the diagnosis is made and therapy prescribed. Particular thought and instruction must be given to the methods and accuracy of administration to insure effective results.

Among the general considerations which should guide the practice of pediatric drug therapy are (1) symptomatic therapy, (2) the use of placebos, and (3) the possible dangers of medication in relation to the potential for benefit.

Specific therapy usually takes precedence over symptomatic therapy, but the value of the latter should not be overlooked. It may confer comfort and sleep to the parents as well as to the child. In most instances the prescription of drugs for a placebo effect should be avoided. The placebo, however, has its place; and all drugs, even specific ones, function to some degree as placebos. Many physicians prescribe drugs simply to give the mother something to do. However, this "something to do" can be bathing, the giving of fluids, and the like; it need not be drugs. The danger involved rests not in the drug itself, but in the possibility that parents will attribute an unwarranted dependence upon "medicine" and that the child may acquire the same unfortunate attitude. In considering these emotional factors one should also be aware that drug therapy may fail except as planned psychotherapy is added. This is especially true in the chronically ill child. The expected

benefits of medicinal therapy should always be balanced against the risks associated with the drug or with its administration. For example, edematous bleeding gingivae in primary herpetic stomatitis often heal better when left alone than after repeated, usually traumatic, local applications. When no drugs are prescribed, it is necessary that a complete explanation be given to the mother or the nurse.

## SPECIFIC CONSIDERATIONS

### THE CHOICE OF DRUGS

It is preferable to become familiar with a few drugs in each category rather than to prescribe a wide variety of similarly acting agents. For those drugs which the physician uses frequently he should know their characteristic routes and rates of absorption, their distribution in the body and their excretion or detoxification. Such information permits some discrimination in selecting a drug when secondary complications preclude the usual choice. For example, one avoids a barbiturate, which is excreted by the kidney, in the presence of renal disease. The normal inadequacy of many physiologic functions in the premature, the newborn and the older infant also affects the choice of drug, its route and frequency of administration and its dosage.

### GENERAL CLASSES OF DRUGS

The scope of this discussion does not permit transcribing complete pharmacologic data. Some of the drugs discussed below are treated more fully in other sections of this book. The drugs listed in this section are grouped according to their desired effect or area of action. Features peculiar to pediatric problems are brought out in the discussion of each group.

### CENTRAL NERVOUS SYSTEM DEPRESSANTS

#### SEDATIVES, HYPNOTICS, ANTICONVULSANTS AND NARCOTICS

The doses of these drugs vary greatly with the condition to be treated, but, in general, the more excited the child, the larger should be the initial dose. The dose should be titrated against effect.

Except in large anesthetic doses, barbitu-

rates are not analgesics and provide little relief for pain. When used alone, they may actually increase excitement of the child in pain. When combined with analgesics, sedatives form a valuable synergistic combination against pain and restlessness. The synergism of sedatives with antipyretics is useful in the prophylaxis of febrile convulsions.

The barbiturates are effective anticonvulsants, and usually should be administered intramuscularly (p. 1122). When administered intravenously, they must be in dilute solutions, and the dose should be titrated against the response. The rectal route is unreliable.

Extreme depression and death have followed average doses of barbiturates administered to patients with poliomyelitis, meningitis, respiratory obstruction or brain tumors. Prolonged but temporary depression also occasionally follows intravenous administration of barbiturates for anesthetic purposes.

Paraldehyde is a particularly safe drug and can be given by a number of routes. Children generally refuse it orally, even in its most palatable form, mixed with an equal quantity of tincture of sweet orange peel and added to sweetened iced water. Paraldehyde has an antibacterial action and can be given intravenously or intramuscularly as it comes in the ordinary bottle. When given intramuscularly to patients with chronic neurologic disturbances, it is liable to cause sloughing of tissue.

Chloral hydrate is another good sedative and soporific. It should not be used when there is gastric, renal or hepatic disease.

Narcotics (morphine, Demerol) are excellent drugs when used in appropriate doses for specific indications (preanesthetic, cardiac failure, and severe pain). The dangers of narcotic drugs in children are not as great as the statements in many textbooks of pharmacology would indicate. Addiction can follow continued use for as short a time as two weeks; the newborn of an addicted mother may also be addicted.

Nalline (nalorphine) is an effective specific antidote for poisoning by opium and its derivatives (morphine, codeine, and the like), Demerol (meperidine), methadone (Dolophine), levorphanol (Levo-Dromoran) and alphaprodine (Nisentil).

#### TRANQUILIZERS, ATARACTICS

Chlorpromazine (Thorazine), meprobamate (Miltown, Equanil), reserpine and other drugs of this class are being used in a number of psychotic and less severe emotional

problems, such as anxiety, tension and restlessness in children, with or without organic disease. Chlorpromazine is also an antiemetic and the drug of choice for the treatment of Sydenham's chorea. It is an antihypertensive agent, but a combination of reserpine and hydralazine is more effective. Meprobamate and others of this group have been used adjuncts in the treatment of enuresis; the value is not adequately defined.

Certain side reactions may be anticipated in the use of these agents. Chlorpromazine has been responsible for jaundice and parainfluenza symptoms. Drowsiness is occasionally encountered. Fever seems to be unrelated to dosage. Nasal congestion may be associated with the use of chlorpromazine or reserpine especially in infants.

#### CENTRAL NERVOUS SYSTEM STIMULANTS

Dexedrine (dextro-amphetamine) and related compounds are used in older children to aid in weight control, but it is doubtful whether there are many instances in which such use is justified. Their central stimulating properties may interfere with sleep and school activity.

The use of xanthines in apnea neonatorum is generally contraindicated. In depressant poisoning (by barbiturates) pentamethylenetetrazol (Metrazol), amphetamine or picrotoxin may be used with other supportive measures. Aminophylline (theophylline with ethylenediamine), if used as a bronchodilator in asthma, may cause central stimulation and poisoning when administered by any route.

#### ANALGESIC AND ANTIPYRETIC DRUGS

These drugs generally serve dual purposes—relieving pain and reducing fever. The value of antipyretics with anticonvulsants as prophylactics against febrile convulsions has been mentioned.

Aspirin is the most frequently used drug of this group. It is a valuable agent, but overdosage results in poisoning, especially when fever and dehydration exist. The potential dangers of preparations of aspirin or other drugs in candy-like form or in too pleasant tasting vehicles may outweigh their advantages.

Acetylamino-phenol (Tempra, Tylenol) is said to be less toxic than the salicylates, but more experience is needed to test this claim. Acetophenetidin (Phenacetin) used alone or in combination (A.P.C., Empirin Compound) has caused methemoglobinemia, particularly in infants.

## ANTIHISTAMINICS

Because it is impossible to be familiar with the available antihistaminics, it is best to limit one's use to a few and especially to those with recommended pediatric dosages. A variety of forms are available: fluid, tablet, capsule, chewing gum and granules (in capsules). The granules may be mixed with food, since they are enteric-coated. Antihistaminics have no value for rhinitis unassociated with allergy. Owing to their anticholinergic property, some antihistaminics are effective for motion sickness. They have varying degrees of sedative effect, a reaction which may prove helpful or annoying.

## ANTIFUNGAL AGENTS

Oral moniliasis (candidiasis) has been treated with a number of agents. Gentian violet should not be used in stronger concentrations than 0.25 per cent. Mycostatin (nystatin) seems to be effective for oral, gastrointestinal and cutaneous moniliasis.

## ANTIMICROBIAL AGENTS (ANTIBIOTICS AND SULFONAMIDES)

This group of drugs is perhaps the most useful and most misused of all therapeutic agents in pediatric practice. The effect of antimicrobial therapy on the shortening of periods of illness, on the avoidance of serious complications, on the reduction of mortality, and even on the prevention of illness constitutes the greatest therapeutic achievement in medical history. At the moment there is urgent need for greater discrimination in selecting the disease to be treated, in selecting the agent or agents to be used, and in determining the dosage and length of treatment.

The dangers inherent in the therapeutic agent itself are both direct and indirect. The direct dangers include damage to tissues by toxic, allergic or mechanical means. The indirect dangers are secondary to development of resistance to the therapeutic agent by existing bacteria, or to the establishment of new bacterial flora, including organisms not susceptible to the agent being administered, or to the establishment of new flora in the gastrointestinal tract which does not permit synthesis of vitamin K. The number of available agents necessitates an increasingly critical attitude toward the management of all patients and certainly toward those who are in the period of growth and development.

Most errors in antimicrobial therapy can

be grouped under three headings: (1) unnecessary therapy, (2) use of wrong agent, and (3) improper dose of the appropriate agent.

The obvious difficulties related to the management of the individual patient are (1) the immediate uncertainties, whether the infection is severe enough to justify specific therapy, and, if so, whether the infection is apt to be caused by an organism susceptible to any of the available antimicrobial agents; (2) the feeling of the physician that he must appear to be doing something for his patient; and (3) the insistence of the patient's parents that a drug be prescribed. The present practice of more or less indiscriminate medication contributes to a noncritical attitude on the part of both physician and layman. The economic saving in the country as a whole would be incalculable if only necessary medication were prescribed.

The use of the wrong antimicrobial agent in a particular situation is related initially to failure to establish an etiologic diagnosis or, when this is impossible, to appreciate the several etiologic possibilities and hence fail to provide therapeutic coverage for them. Subsequently the error lies in persistence of initially prescribed therapy when the clinical course has not been favorably affected. In the management of a child acutely ill with an infectious disease for which antimicrobial therapy is deemed necessary, the administration of it should not be delayed until bacteriologic identification is available, but appropriate material such as nasopharyngeal swabs and specimens of cerebrospinal fluid, blood, and/or urine should be obtained for smear and/or culture (including bacterial sensitivity to the commonly used antibiotics) before therapy is instituted. The initial selection of the antimicrobial agent(s) should be based on coverage of the most likely pathogens. Such decisions are particularly important in serious infections such as meningitis, osteomyelitis, septicemia, and any infection in the newborn infant. When laboratory data are available and response of the culture to the initially prescribed antimicrobial agent(s) has been observed, the decision can be made for continuation or change in the therapeutic program.

Inadequate therapy with an appropriate antimicrobial agent is usually the result of too small doses or too short a period of administration, or both. Such therapy may, on occasion, have disastrous results. The organism is not eliminated, but simply temporarily

suppressed. There may be a favorable initial response, followed by an exacerbation after therapy has been stopped. In such instances the clinical pattern may be sufficiently altered to be responsible for a delay in recognizing that the infection is still active. There are now a sufficient number of instances of chronic osteomyelitis and of permanent cerebral damage (from inadequately treated meningitis) to make it clear that suppressive in contrast to curative therapy is a major problem of the moment.

Chemotherapeutic agents may also be used prophylactically, but in general such use is not advisable. The use of penicillin to prevent initial and recurrent attacks of rheumatic fever is, however, generally accepted.

The use of a single antibiotic is generally preferable to a combination of several of them. When it is thought to be necessary to provide broader coverage than is possible with a single antibiotic, then the ones chosen should be prescribed individually and not in a commercially prepared combination. Combinations of penicillin and streptomycin as supplied commercially contain excessive streptomycin for infants when doses are calculated by penicillin content.

### CARDIAC GLYCOSIDES

Since these are potent and potentially dangerous drugs, preparations should be used which are primarily intended for pediatric patients. The preparations intended for adult use are usually too concentrated to allow accurate measurements for infants.

### CATHARTICS

These drugs are used more indiscriminately than any others readily available to the public. They should be used only when indicated, and then for a short time. There are extreme differences in individual responsiveness to the cathartics. In the few instances in which prolonged administration is indicated it is wise to start with a small dose and

increase it gradually as needed. Efforts should be made meanwhile to correct the underlying difficulty by means of improvements in diet and in toilet habits; the dose of the drug should then be gradually reduced until administration of the drug is discontinued.

### EMETICS

One or two teaspoonfuls of fresh ipecac syrup (U.S.P.) is an effective emetic. Some physicians recommend that it be kept in homes where there are infants and toddlers to be used in case of accidental poisoning or of croup. It is more effective than lavage in emptying the stomach, but there is also the risk of aspiration. If the vomiting center has been depressed by poisons (e.g., morphine), ipecac is dangerous in that the emetine retained may be toxic to the heart. Emetics are also dangerous in caustic or alkali poisoning.

### THE CALCULATION OF DOSES

Many rules exist for determining the dose of a drug for patients of various ages and weights. The multiplicity of these rules is evidence that no single rule is entirely satisfactory. Those most frequently used are listed at the bottom of the page.

Doses based on the factor of age have limited application; when the patient is usually heavy or light, the error may be considerable. Doses determined by the factor of weight also have limitations; for example, a dose calculated on the basis of a given amount of drug per unit of body weight may be satisfactory for infants, but excessive for older children.

Crawford and others have noted a close correlation of many physiologic processes when expressed in terms of surface area of the body. Doses of drugs can also be determined by this method, which is applicable for patients of various ages and weights. It is anticipated that drug dosage expressed in terms of  $D \times M$  (where  $D$  is the amount of drug per square meter of body surface and

Fried's Rule:

$$\frac{\text{Age in months}}{150} \times \text{Adult dose} = \text{Approximate dose for infants up to 2 years of age}$$

Clark's Rule:

$$\frac{\text{Wgt. in pounds}}{150} \times \text{Adult dose} = \text{Approximate dose for children over 2 years of age}$$

Young's Rule:

$$\frac{\text{Age in years}}{\text{Age in years plus 12}} \times \text{Adult dose} = \text{Approximate dose for children over 2 years of age}$$

FIG. 36. Nomogram for estimation of surface area. The surface area is indicated when a straight line which connects the height and weight levels intersects the surface area column; or if the patient is roughly of average size, from the weight alone (in-closed area). (Nomogram modified from data of E. Lloyd by C. D. West.)

the surface area of the patient in square meters) will be more adequate for infants and children and perhaps for adults.

The surface area of a patient can be derived from a nomogram using the height and weight or, when the patient approximates average size, by using a weight-surface area nomogram (Fig. 36).

Doses based on surface area can be calculated by one of the rules listed at the bottom of the page.

Table 43 gives doses of frequently used drugs per square meter of body surface as well as by other standards.

By whatever method a dose is calculated, the result should be considered only an "average dose." It may not be the correct dose for a particular patient, although it is satisfactory for most patients of equal age and size.

Some drugs produce definite and visible

evidence of their effects; others require laboratory tests such as blood or urine analysis for evaluating the correctness of the dose. After the effect of the initial dose or doses has been noted subsequent doses should be adjusted to the individual patient's needs.

**PRESCRIPTION OF DRUGS**

Drugs should not be ordered in odd quantities. For example, 0.45 cc. should be expressed as 0.5 cc.; such a practice tends to prevent errors. For treatment of a child in his home it is advisable to prescribe only the amount of a drug estimated to be sufficient for a particular illness.

A teaspoonful is usually considered to be 4 to 5 ml. Since the capacity of teaspoons varies from 3.8 to 7.8 ml., the mother should be advised to select a teaspoon for administration of a prescribed drug which holds a quantity nearly equal to that of a standard measuring teaspoon. Prescriptions for drugs in liquid vehicles should then be written so that a single dose is contained in a full teaspoon rather than in a fraction of it. Similarly, drops vary considerably in size, dependent upon the aperture of the dropper. Calibrated droppers, now available, provide greater accuracy than the use of drops. See Appendix for list of common household measures.

Confusion can be avoided by adequately discussing the plan of therapy with the mother or nurse and by giving them written directions.

**ROUTES OF ADMINISTRATION**

The appropriate dose and frequency of administration of most drugs are closely related to the route by which they are to be administered. Some drugs, such as insulin, are effective by only one route.

**The Oral Route.** This is the preferred route, and should be used whenever practical. When there are gastrointestinal disturbances, such as anorexia, nausea or vomiting, some other route should be selected. Hours may be lost if a drug is given orally and vomiting ensues. When there is some doubt about the functional integrity of the oral route, the initial dose or doses may be given parenterally, and the drug may be administered orally as soon as it is deemed practical. (Text continued on page 227.)

$$\frac{\text{Surface area of patient in sq. meters}}{1.73 \text{ (adult surface area)}} \times \text{Adult dose} = \text{Dose for the patient}$$
$$\text{Surface area of patients in sq. meters} \times \text{Dose per sq. meter} = \text{Dose for the patient}$$

Table 43. Drugs and Drug Doses

<i>Drug</i>	<i>Dose</i>	<i>Supplied</i>
Acetaminophen (N-acetyl-p-aminophenol) (Tempra, Tylenol)	Under 1 year: 60 mg. 1-4 years: 60-120 mg. 4-8 years: 120-240 mg. 8-12 years: 240 mg. Single dose repeated every 6 hours (0) 0.7 gm./M <sup>2</sup> /24 hours, divided into 4-6 doses (0)	Tempra: Drops: 60 mg./0.6 ml. Syrup: 120 mg./5 ml. Tylenol: Drops: 60 mg./0.6 ml. Elixir: 120 mg./5 ml.
Acetylsalicylic acid (Aspirin)	Antipyretic: 65 mg./kg./24 hours 1.5 gm./M <sup>2</sup> /24 hours Maximum: 3.6 gm./24 hours Divided into 4-6 doses (0 or R) Avoid overdosage, particularly in infants To obtain salicylate level of 20 mg./100 ml. of blood: 3.0 gm./M <sup>2</sup> /24 hours (0)	Supplied in many forms Tablets: 30, 60, 75, 300 mg. ( $\frac{1}{2}$ , 1, $1\frac{1}{4}$ , 5 grains)
Adrenocorticotrophic hormone (Corticotropin, ACTH)	Infants: 20-40 units/24 hours Children: 1-2 units/kg./24 hours 50-100 units/M <sup>2</sup> /24 hours Aqueous: Divided into 4 doses I.M. Gel: I.M. once daily See individual diseases	Aqueous: Vials: 25, 40 units/ml. Ampules: 10 units/ml. Gel: Vials: 20, 40, 80 units/ml. Cartridge: 40 units/ml.
Amethopterin (Methotrexate)	Under 2 years: 1.25 mg./24 hours (0) 2-6 years: 2.5 mg./24 hours (0) Over 6 years: 5.0 mg./24 hours (0) CAUTION: Toxic	Tablets: 2.5 mg.
Aminophylline (Theophylline with ethylenediamine)	15 mg./kg./24 hours 0.5 gm./M <sup>2</sup> /24 hours Divide into 4 doses (I.V. or I.M.) Rectal dose: double the above dose Poisonous by all routes in overdosage	I.V.: 10-ml. ampules-0.25 gm. 20-ml. ampules-0.5 gm. I.M.: 2-ml. ampules-0.5 gm. R: Suppositories 0.125, 0.25 and 0.5 gm.
Ammonium chloride	75 mg./kg./24 hours 2.0 gm./M <sup>2</sup> /24 hours Divided into 4 doses (0) May produce acidosis by continued use	Tablets: 0.3 gm. (5 grains) Tablets enteric: 0.5 gm. ( $7\frac{1}{2}$ grains) 1.0 gm. (15 grains) Solutions and syrups
Ammonium mandelate	250 mg./kg./24 hours 6-8 gm./M <sup>2</sup> /24 hours Divided into 4 doses (0)	As chemical for solutions and syrups
<p>Key: M<sup>2</sup>, dose per square meter of body surface.</p> <p>I.M., intramuscular. I.Th., intrathecal. I.V., intravenous.</p> <p>O, oral. R, rectal. S.C., subcutaneous. T, topical.</p>		

All doses are average ones and are approximate. Variability of response may require alteration of dosage. Doses based on different criteria (body weight, surface area, and so forth) frequently do not correspond.

To change the dose per kilogram to the dose per pound, divide the dose by 2.2 (or, more conveniently, by 2). To change the dose in grams per kilogram to grains per pound, multiply the dose in grams per kilogram by 7.

Table 43. Drugs and Drug Doses (*continued*)

<i>Drug</i>	<i>Dose</i>	<i>Supplied</i>
mobarbital sodium (Amytal)	Same as Phenobarbital	Ampules: 65 mg. (1 grain) 125 mg. ( $1\frac{7}{8}$ grains) 250 mg. ( $3\frac{3}{4}$ grains) 500 mg. ( $7\frac{1}{2}$ grains)
amphetamine sulfate (Benzedrine)	7.5–25 mg./24 hours 15 mg./M <sup>2</sup> /24 hours Divided into 3 doses or as Spansule in single dose (0)	Tablets: 5 and 10 mg. Spansules: 5, 10 and 15 mg.
amphotericin B (Fungizone)	0.25 mg./kg./24 hours Single dose diluted, 1 mg./10 ml. (I.V.) CAUTION: Toxic	Vials: 50 mg.
amprolisen (Pentolinium tartrate)	1.0 mg./kg./24 hours 30 mg./M <sup>2</sup> /24 hours Divided into 3 doses waking hours (O, S.C. or I.M.) Starting dose	Tablets: 20, 40 and 100 mg. Vials: 10 mg./ml.
Atropine sulfate	0.01 mg./kg./dose 0.3 mg./M <sup>2</sup> /dose Maximum: 0.4 mg. Preanesthetic or every 4–6 hours (S.C.)	Tablets: Several sizes Vials: 1 ml. = 0.4 mg. (1/150 grain)
Avertin (Tribromoethanol solution)	As single dose (R) in 3% sol.: 75 mg./kg. 2.0 gm./M <sup>2</sup>	Solution (U.S.P.): 1.0 gm./ml.
Bacitracin	For enteric infections: 500–2000 units/kg./24 hours, divided into 4–6 doses (0) 600–1200 units/kg./24 hours Maximum: 100,000 units Divide into 3–4 doses (I.M.)	1 mg. (50 units)
BAL (Dimercaprol, British Anti-Lewisite)	For arsenic, mercury and gold poisoning, in the following order: 2 mg./kg./every 4 hours for 2–4 doses (I.M.) 3 mg./kg./every 4 hours for 2 days (I.M.) 3 mg./kg./every 6 hours for 1 day (I.M.) 3–4 mg./kg./every 12 hours for 7–10 days (I.M.)	4.5-ml. ampules 10% in oil (100 mg./ml.)
Banthine (Methantheline bromide)	6 mg./kg./24 hours 150 mg./M <sup>2</sup> /24 hours Divided into 4 doses (O or I.M.)	Tablets: 50 mg. (scored) Ampules: 50 mg.
Barbiturates	See individual drugs	
Belladonna tincture	0.1 ml./kg./24 hours Not to exceed 3.5 ml./day 2.5 ml./M <sup>2</sup> /24 hours Divided into 3–4 doses (0)	Tincture (U.S.P.): 1 ml. = about 0.3 mg. of atropine (1/200 grain) Calibrated vitamin droppers offer accurate dosage

Table 43. Drugs and Drug Doses (*continued*)

<i>Drug</i>	<i>Dose</i>	<i>Supplied</i>
Benadryl (Diphenhydramine hydrochloride)	5 mg./kg./24 hours Not to exceed 150 mg./ day 120 mg./M <sup>2</sup> /24 hours Divided into 4 doses (O or I.M.)	Capsules: 25 and 50 mg. Tablets enteric: 50 mg. Elixir: 10 mg./4 ml. Ampules: 50 mg./ml. Vials: 50 mg./ml.
Benodaine (Piperoxan)	Test dose: 0.25 mg./kg. (I.V.) 10 mg./M <sup>2</sup> (I.V.) Maximum: 20 mg.	Ampules: 2 mg./ml.
Bromides	60 mg./kg./24 hours 1.5 gm./M <sup>2</sup> /24 hours Divide into 3 doses (O)	Supplied in many forms
Caffeine with sodium benzoate	8 mg./kg./dose 250 mg./M <sup>2</sup> /dose Maximum: 500 mg. Repeat every 4 hours p.r.n. (S.C., I.V. or I.M.)	Ampules: 0.25 gm. (3 <sup>3</sup> / <sub>4</sub> grains) 0.5 gm. (7 <sup>1</sup> / <sub>2</sub> grains)
Calcium chloride (27% calcium)	0.40 gm./kg./24 hours 8.0 gm./M <sup>2</sup> /24 hours Give as 2% solution Divide into 4 doses every 6 hours (O) CAUTION: Acidifying. Give 2-3 days, then change to another calcium salt	Supplied as solutions of desired strength Ampules: 10%
Calcium disodium versenate (Edathamil calcium-sodium) (EDTA)	30-75 mg./kg./24 hours 1.7 gm./M <sup>2</sup> /24 hours Divide into 2 doses (I.V. or S.C.) I.V.: diluted to 0.2-0.4% solution S.C.: diluted to 2.5% solution Course: 2 doses/24 hours for 3 days; rest interval of 2 days Repeat course if needed	Ampules: 200 mg./ml.
Calcium gluconate (9% calcium)	0.5 gm./kg./24 hours 12.0 gm./M <sup>2</sup> /24 hours Divided doses (O or I.V.) I.V., diluted. Give slowly CAUTION: Bradycardia. Local necrosis with leakage from vein	Powder Ampules: 10% solution (I.V. only)
Calcium lactate (13% calcium)	0.5 gm./kg./24 hours 12 gm./M <sup>2</sup> /24 hours Divided doses (O)	Powder

Key: M<sup>2</sup>, dose per square meter of body surface.

I.M., intramuscular.

I.Th., intrathecal.

I.V., intravenous.

O, oral.

Chloramphenicol (Chloromycetin)	<p>50–100 mg./kg./24 hours 1.5–3.0 gm./M<sup>2</sup>/24 hours</p> <p>Intervals: 4–6 hours (O) 6–8 hours (I.V.) 8–12 hours (I.M.)</p>	<p>Capsules: 50, 100 and 250 mg.</p> <p>Palmitate: 125 mg./4 ml.</p> <p>I.V.: 0.5-gm. ampules (diluted before use for I.V. drip)</p> <p>I.M.: 1.0-gm. vials</p> <p>Topical: Many forms</p>
Chlor-Trimeton (Chlorphenpyridamine maleate)	<p>0.35 mg./kg./24 hours 10.0 mg./M<sup>2</sup>/24 hours Divided into 4 doses</p>	<p>Tablets: 4 mg.</p> <p>Repetabs: 8 and 12 mg.</p> <p>Syrup: 2 mg./5 ml.</p> <p>Injection: 1-ml. ampules (10 mg./ml.) 2-ml. ampules (100 mg./ml.)</p> <p>Teldrin Spansules: 8 and 12 mg.</p>
Codeine	<p>For pain: 3 mg./kg./24 hours 100 mg./M<sup>2</sup>/24 hours Divide into 6 doses (O or S.C.)</p> <p>For cough: <math>\frac{1}{3}</math>–<math>\frac{1}{2}</math> above dose</p>	<p>Tablets: Many forms</p> <p>Cough syrups often contain 10 mg./5 ml.</p>
Compazine (Prochlorperazine)	<p>0.5 mg./kg./24 hours 10 mg./M<sup>2</sup>/24 hours Divide into 3 or 4 doses (O or R) I.M. dose: half of oral dose CAUTION: Catatonia or parkinsonian symptoms with overdose</p>	<p>Spansules: 10 and 15 mg.</p> <p>Suppositories: 5 and 25 mg.</p> <p>Syrup: 5 mg./5 ml.</p> <p>Tablets: 5 and 10 mg.</p> <p>Ampules: 5 mg./ml.</p> <p>Vials: 5 mg./ml.</p>

Table 43. Drugs and Drug Doses (continued)

Drug	Dose	Supplied
Cortisone acetate	General use: Dosage varies with patient, disease and response  See individual diseases	Tablets: 5, 10 and 25 mg. Injection: 25 and 50 mg./ml.
Darvon (Dextro propoxyphene hydrochloride)	3 mg./kg./24 hours 100 mg./M <sup>2</sup> /24 hours Divide into 4-6 doses (O)	Capsules: 32 and 65 mg.
Demerol (Meperidine hydro- chloride)	6 mg./kg./24 hours 175 mg./M <sup>2</sup> /24 hours Maximum: 100 mg./dose Divide into 6 doses/24 hours (O, I.M. or S.C.)	Tablets: 50 and 100 mg. Elixir: 50 mg./5 ml. Ampules: 50 mg./ml. Vials: 50 mg./ml.
Deslanoside (Lanatoside C) (Cedilanid)	Digitalizing dose (rapid): 0.030 mg./kg. 0.75 mg./M <sup>2</sup> Best I.V. or I.M. In divided doses: Or as emergency: Single dose Patient should not have had digitalis or deriva- tives for 2 weeks or more Give slowly I.V. Watch EKG. Redigitalize with digitoxin or Digoxin after 24 hours	Cedilanid D ampules: 0.2 mg./ml.
Desoxycorticosterone acetate (DOCA)	1-5 mg./24 hours 1.5-2.0 mg./M <sup>2</sup> /24 hours Single dose in oil (I.M.)	Oil: 5 mg./ml. Aqueous: 5 mg./ml. Repository: 25 mg./ml.
Dexedrine sulfate (Dextro-amphetamine sulfate)	7.5-15 mg./24 hours 10-15 mg./M <sup>2</sup> /24 hours Divide into 3 doses/24 hours or as delayed action in single dose (O)	Tablets: 5 mg. Spansules: 5, 10 and 15 mg. Elixir: 5 mg./5ml.
Diamox (Acetazolamide)	10-30 mg./kg./24 hours 0.5 gm./M <sup>2</sup> /24 hours Single dose/24 hours or divide into 3 doses/24 hours (O or I.V.)	Tablets: 250 mg. Ampules: 500 mg.

Key: M<sup>2</sup>, dose per square meter of body surface.  
I.M., intramuscular.  
I.Th., intrathecal.  
I.V., intravenous

O, oral.  
R, rectal.  
S.C., subcutaneous.  
T, topical.

Table 43. Drugs and Drug Doses (continued)

Drug	Dose	Supplied
digitalis (Leaf)	Digitalizing dose: Under 1 year of age: 0.045 gm./kg. 1-2 years: 0.040 gm./kg. Over 2 years: 0.030 gm./kg. 0.75 gm./M <sup>2</sup> Patient should not have had digitalis or derivatives for 2 weeks or more Divide total dose into 3, 4 or more portions with 6 hours or more between doses (O, I.V. or I.M.) Maintenance dose: Give 1/10 of digitalizing dose daily	Tablets: 0.1 gm. and fractions Tincture: 1 ml. = 0.1 gm. Digifolin: Ampules—50 mg./ml.
digitoxin	Digitalizing dose: Under 1 year of age: 0.045 mg./kg. 1-2 years: 0.04 mg./kg. Over 2 years: 0.03 mg./kg. 0.75 mg./M <sup>2</sup> /24 hours Patient should not have had digitalis or derivatives for 2 weeks or more Divide total dose into 3, 4 or more portions with 6 hours or more between doses (O, I.V. or I.M.) Maintenance dose: Give 1/10 of digitalizing dose daily	Tablets: 0.1, 0.15 and 0.2 mg. Ampules: 0.2 mg./ml.
digoxin	Digitalizing dose: Under 2 years of age: 0.09-0.12 mg./kg. Over 2 years: 0.045-0.09 mg./kg. 1.5 mg./M <sup>2</sup> Patient should not have had digitalis or derivatives for 2 weeks or more Divide total dose into 3, 4 or more portions with 6 hours or more between doses (O, I.V. or I.M.) Maintenance dose: Give 25% of digitalizing dose once daily	Tablets, scored: 0.25 and 0.5 mg. Elixir: 0.05 mg./ml. Ampules: 0.25 mg./ml.
digoxin (Diphenylhydantoin sodium)	3-8 mg./kg./24 hours 100-200 mg./M <sup>2</sup> /24 hours Divide into 3 doses (O or I.M.)	Tablets: 50 mg. (3/4 grain) Capsules: 30 and 100 mg. (1/2 and 1 1/2 grains) Suspension: 100 mg./4 ml. Vials: 50 mg./ml.

Table 43. Drugs and Drug Doses (*continued*)

<i>Drug</i>	<i>Dose</i>	<i>Supplied</i>
Diocetyl sodium sulfosuccinate (Colace, Doxinate)	5 mg./kg./24 hours 150 mg./M <sup>2</sup> /24 hours Divide into 3 or 4 doses (O) Enema: Add 50–100 mg. to flushing enema (R)	Capsules: 50 and 100 mg. Liquid: 10 mg./ml. Syrup: 30 mg./5 ml.
Diuril (Chlorothiazide)	0.01–0.04 gm./kg./24 hours 0.3–1.2 gm./M <sup>2</sup> /24 hours Single dose or divided every 6 or 12 hours (O)	Tablets (scored): 250 and 500 mg.
Dramamine (Dimenhydrinate)	5 mg./kg./24 hours 120 mg./M <sup>2</sup> /24 hours Maximum: 150 mg./24 hours Divide into 4 doses (O, R or I.M.)	Tablets: 50 mg. Suppositories: 100 mg. Liquid: 12.5 mg./4 ml. Ampules: 50 mg./ml.
Ecolid (Chlorisondamine chloride)	First day: 15 mg./M <sup>2</sup> in morning (O) Second day: 15 mg./M <sup>2</sup> in morning (O) 15 mg./M <sup>2</sup> at night (O) Increase 15 mg./M <sup>2</sup> to gain effect Add hydralazine or reserpine for maximal control with minimal side effects	Tablets: 10, 25 and 50 mg. Ampules: 5 mg./ml.
Ephedrine sulfate	3 mg./kg./24 hours 100 mg./M <sup>2</sup> /24 hours Maximum, 30 mg./dose Divide into 4–6 doses/24 hours (O, S.C. or I.V.)	Capsules, Tablets: 25 and 50 mg. Syrup: 15 mg./4 ml. Ampules: 25 and 50 mg./ml.
Epinephrine hydrochloride (Adrenalin chloride)	Asthma or tolerance test: 1:1000 aqueous: 0.01 ml./kg./dose 0.3 ml./M <sup>2</sup> /dose Maximum, 0.5 ml. Repeat every 4 hours p.r.n. (S.C.) 1:100 aqueous: By nebulizer p.r.n. 1:500 oil: 0.01–0.02 ml./kg. 0.3–0.6 ml./M <sup>2</sup> Daily or every 12 hours (I.M.)	1:1000 aqueous: Ampules: 1 ml. Vials: 30 ml. Bottles: 30 ml. 1:100 aqueous: 5 ml. bottles 1:500 oil Ampules: 1 ml.

Key: M<sup>2</sup>, dose per square meter of body surface.

I.M., intramuscular.

I.Th., intrathecal.

I.V., intravenous.

O, oral.

R, rectal.

S.C., subcutaneous.

T, topical.

Table 43. Drugs and Drug Doses (continued)

Drug	Dose	Supplied
tythromycin (lilotycin, Erythrocin)	20–50 mg./kg./24 hours 0.75–1.5 gm./M <sup>2</sup> /24 hours Divide into 4 doses/24 hours (O, I.V. or I.M.)	Tablets: 100 and 250 mg. Suspension: 100 and 200 mg./5 ml. Drops (oral): 5 mg./drop Ampules: 0.25, 0.5 and 1.0 gm. Vials: 50 mg./ml.
rous sulfate	Requirement: 6–16 mg. elemental iron (O) Anemia therapy: 100–200 mg. elemental iron/24 hours 0.5–1.0 gm. ferrous sulfate/24 hours Divide into 3 doses (O)	Ferrous sulfate: Tablets: 0.3 gm. Syrup: 0.20 gm./5 ml. (elemental iron): 0.04 gm./5 ml. Fer-in-Sol: Ferrous sulfate: 125 mg./ml. (elemental iron): 25 mg./ml.
radantin (Nitrofurantoin)	7.5 mg./kg./24 hours 200 mg./M <sup>2</sup> /24 hours Divide into 4 doses/24 hours (O)	Tablets: 50 and 100 mg. Oral suspension: 25 mg./5 ml.
gamma globulin (Immune globulin)	Hypogammaglobulinemia: 1 ml./kg. every 2–4 weeks (I.M. only) Measles: Preventive dose: 0.22 ml./kg. Attenuation: 0.05 ml./kg. (I.M. only) Hepatitis: Preventive dose: 0.022 ml./kg. (I.M. only)	16% solution U.S.P.
antrisin (Sulfisoxazole)	150 mg./kg./24 hours 4.5 gm./M <sup>2</sup> /24 hours Divide into 4 doses (O) 2.5 gm./M <sup>2</sup> /24 hours (I.V. or I.M.) Initial dose (loading) equals ½ of daily dose	Tablets (scored): 0.5 gm. Suspension: 0.5 gm./5 ml. Syrup: 0.5 gm./5 ml. Lipograntrisin: 1.0 gm./5 ml. Ampules: 2.0 gm./5 ml. 4.0 gm./5 ml.
Gentian violet (Methylosaniline)	Oral Monilia: Aqueous, 0.25–1% 3-day courses, (T), t.i.d. As coated tablets: 2 mg./kg./24 hours 50 mg./M <sup>2</sup> /24 hours Divide into 2–3 doses/24 hours (O) Treat 7–10 days Rest 7–10 days CAUTION: Not to be chewed	Tablets (coated): 10 and 30 mg.
Heparin	0.5 mg./kg. stat and every hour (I.V. drip) Check clotting time Titrate dose to yield 20–30 minute clotting time Continuous I.V.: 0.1 mg./ml. Antidote: Protamine sulfate (I.V. diluted) 5–8 mg./kg./24 hours	Ampules: 10 mg./ml.

Table 43. Drugs and Drug Doses (continued)

Drug	Dose	Supplied
Hetrazan (Diethylcarbamazine)	Filariasis: 6 mg./kg./24 hours 150 mg./M <sup>2</sup> /24 hours (O) Divide into 3 doses/day Treat 7-10 days Ascariasis: 15 mg./kg./24 hours 500 mg./M <sup>2</sup> /24 hours (O) Single daily dose for 4 consecutive days	Tablets: 50 mg. Syrup: 120 mg./5 ml.
Hexylresorcinol	0.1 gm./year of age Maximum, 1.0 gm. Single dose (O) May repeat 3 days CAUTION: Not to be chewed	Crystoids: 0.1 and 0.2 gm.
Hydralazine (Apresoline)	0.15 mg./kg. 4 mg./M <sup>2</sup> With reserpine for hypertension Single dose every 12-24 hours (I.M.)	Tablets: 10, 25, 50 and 100 mg. Ampules: 20 mg./ml.
Hydrocortisone	$\frac{2}{3}$ of cortisone dose	Tablets: 5, 10 and 20 mg. Oral suspension: 10 mg./5ml. Ophthalmic suspension: 0.5-2.5% Topical: 1% Vials: For dilution, I.V.: 2-ml. vials 100 mg./ml. and 100 mg./20 ml. For I.M.: 5-ml. vials 50 mg./ml. Intra-articular: 5-ml. vials 20-50 mg./5 ml.
Imferon	Surface area in M <sup>2</sup> $\times$ 55 $\times$ (12.5—observed Hb.) = mg. of iron (I.M.) Add 20% for storage (Formula useful under age 3-4 years)	Equivalent of: 50 mg. elemental iron/ml.
Inversine (Mecamylamine hydrochloride)	Adult dose: 2.5 mg. twice daily p.c. (O) Increase 2.5 mg. at intervals of 2 or more days to response Average total adult dose: 25 mg. 1.5 mg./M <sup>2</sup> /24 hours Divide into 2 doses, p.c. (O) Increase to 15 mg./M <sup>2</sup> /24 hours	Tablets: 2.5 and 10 mg.
Ipecac syrup	Emetic dose: 5-10 ml. (O) Repeat in 20-30 minutes if needed	Syrup U.S.P.

Key: M<sup>2</sup>, dose per square meter of body surface.  
 I.M., intramuscular.  
 I.Th., intrathecal.  
 I.V., intravenous.

O, oral.  
 R, rectal.  
 S.C., subcutaneous.  
 T, topical.

Table 43. Drugs and Drug Doses (continued)

Drug	Dose	Supplied
niazid	5-15 mg./kg./24 hours 350 mg./M <sup>2</sup> /24 hours 3-4 doses/day (O or I.M.)	Tablets: 50 and 100 mg. Capsules: 50 and 100 mg. Syrup: 50 mg./5 ml. Ampules: 100 mg./ml.
namycin sulfate (Kantrex)	Systemic infections: 10-20 mg./kg./24 hours 0.5 gm./M <sup>2</sup> /24 hours Severe: up to 100 mg./kg./24 hours 3.0 gm./M <sup>2</sup> /24 hours Divide into 2-4 doses/24 hours (I.M.) Toxic reactions: Casts, red and white blood cells in urine; albuminuria; tinnitus, vertigo, deafness; skin eruptions; neutropenia Intestinal infections: 50 mg./kg./24 hours 1.5 gm./M <sup>2</sup> /24 hours Divide into 4 doses (O)	Vials: 0.5 gm. in 2 ml. 1.0 gm. in 3 ml. Capsules: 0.5 gm.
evarterenol bitartrate (Levophed, Norepinephrine)	1.0 ml. of 0.2% solution (0.1% base) in 250 ml. diluent Drip at 0.5 ml./min. to give 2 micrograms (base)/minute 2 micrograms/M <sup>2</sup> /minute Titrate dose with blood pressure CAUTION: Slough results from extravascular leakage	4-ml. ampules (0.2%)
magnesium hydroxide (Milk of magnesia)	Cathartic: 0.5 ml./kg./dose (O) 15.0 ml./M <sup>2</sup> /dose (O)	U.S.P. magma
magnesium sulfate (Epsom salt)	Cathartic: 0.25 gm./kg./dose (O) 8.0 gm./M <sup>2</sup> /dose (O) Hypertension: Intramuscular—50% solution: 0.1-0.2 ml./kg./dose 5 ml./M <sup>2</sup> /dose Repeat every 4-6 hours p.r.n. (I.M.) Intravenous—3% solution: 175 mg./kg./dose 5.8 ml./kg./dose 5 gm./M <sup>2</sup> /dose 170 ml./M <sup>2</sup> /dose I.V. during 1 hour	Ampules: 50%
Mandelamine	0.1 gm./kg./24 hours initially, then 0.05 gm./kg./24 hours 3.0 gm./M <sup>2</sup> /24 hours initially, then 1.5 gm./M <sup>2</sup> /24 hours Maximum, 3.0 gm./24 hours Divide into 3 doses/24 hours (O)	Tablets: 0.5 gm. Enteric coated: 0.25 gm.
Mebaral (Mephobarbital)	Same as Phenobarbital	Tablets: 30, 45, 100 and 200 mg.
Meproamate (Miltown, Equanil)	25 mg./kg./24 hours 0.7 gm./M <sup>2</sup> /24 hours Divide into 2-3 doses/24 hours (O)	Tablets: 200 and 400 mg. Suspension: 200 mg./5 ml.

Table 43. Drugs and Drug Doses (*continued*)

<i>Drug</i>	<i>Dose</i>	<i>Supplied</i>
Mercaptomerin sodium (Thiomerein sodium) Meralluride sodium (Mercuryhydrin)	Below 6 kg.: 0.25–0.50 ml. (I.M.) Above 6 kg.: 0.50–1.0 ml. (I.M.) 1.0 ml./M <sup>2</sup> /24 hours (I.M.)	Ampules to yield 0.13 gm./ml.
6-Mercaptopurine (Purinethol)	Start: 2.5 mg./kg./24 hours single dose (O) Increase to 5 mg./kg./24 hours in 4 weeks if no response	Tablets: 50 mg.
Mesantoin	3–10 mg./kg./24 hours 100–300 mg./M <sup>2</sup> /24 hours Divide into 3 doses/24 hours (O)	Tablets: 100 mg.
Methimazole (Tapazole)	Start: 0.4 mg./kg./24 hours 12 mg./M <sup>2</sup> /24 hours Maintenance: 0.2 mg./kg./24 hours 6 mg./M <sup>2</sup> /24 hours Divide into 3 doses/24 hours (O)	Tablets: 5 and 10 mg.
Methylene blue	Methemoglobinemia: 0.2 ml./kg./dose 5 ml./M <sup>2</sup> /dose 1% solution (I.V.) Give over 5 minutes	Ampules: 1%
Metrazol (Pentylentetrazol)	0.2 ml./kg./dose Not over 5.0 ml. 5.0 ml./M <sup>2</sup> /dose Diluted (I.V.) Dose for marked barbiturate depression may be repeated every 15 minutes p.r.n.	Tablets: 100 mg. Ampules: 100 mg./ml.
Morphine sulfate (Paregoric yields 0.4 mg. of morphine/ml.)	Analgesic: Preoperative: 0.1–0.2 mg./kg./dose (S.C.) Maximum, 15 mg.	Stock tablets or solution
Mysoline (Primidone)	Infants and small children: 125 mg. b.i.d. and t.i.d. Over age 8 years: Up to 250 mg. t.i.d. 1.5 gm./M <sup>2</sup> /24 hours (maximum) Divide into 2–3 doses (O)	Tablets (scored): 0.25 gm. Suspension: 0.25 gm./5 ml.
Nalorphine hydrochloride (Nalline)	0.1–0.2 mg./kg./dose (I.V. or I.M.) May repeat in 15 minutes	Ampules: 5 mg./ml. Ampules for neonatal use: 0.2 mg./ml.

Key: M<sup>2</sup>, dose per square meter of body surface.

I.M., intramuscular.

I.Th., intrathecal.

I.V., intravenous.

O, oral.

R, rectal.

S.C., subcutaneous.

T, topical.

Table 43. Drugs and Drug Doses (*continued*)

<i>Drug</i>	<i>Dose</i>	<i>Supplied</i>
embutal (Pentobarbital sodium)	Same as Phenobarbital	Capsules: 30, 50 and 100 mg. Suppositories: 30, 60, 120 and 200 mg. Elixir: 15 mg./4 ml. Ampules: 50 mg./ml. Vials: 50 mg./ml.
Neomycin sulfate	50-100 mg./kg./24 hours 1.5-3.0 gm./M <sup>2</sup> /24 hours Divided doses 4-6 times/24 hours (O) 7.5-15 mg./kg./24 hours 200 mg./M <sup>2</sup> /24 hours Divided doses 4-6 times/24 hours (I.V.) CAUTION: Toxic (I.V.)	Tablets: 0.5 gm. Mycifradin Pediatric Solution: 25 mg./ml. Vials: 0.5 gm.
Neostigmine (Prostigmin Bromide)	1-2 mg./kg./24 hours 30-50 mg./M <sup>2</sup> /24 hours Divided doses 3-6 times/24 hours (O)	Tablets: 15 mg.
(Prostigmin Methyl- sulfate)	0.04 mg./kg./dose (I.M.) 1.0 mg./M <sup>2</sup> /dose (I.M.)	Ampules: 0.25 mg./ml. (1:4000) 0.5 mg./ml. (1:2000)
Nikethamide (Coramine)	0.10 ml./kg./dose 3.0 ml./M <sup>2</sup> /dose Maximum, 10 ml. 25% solution (I.V. or I.M.) Repeat as needed	Ampules: 25%
Nitrogen mustard (Mustargen Hydrochloride)	0.1 mg./kg./24 hours for 4 days (I.V.) CAUTION: Toxic—slough if extravascular leak	Ampules: 10 mg.
Novobiocin (Albamycin, Cathomycin)	20-50 mg./kg./24 hours 0.75-1.5 gm./M <sup>2</sup> /24 hours Divided doses every 4-6 hours (O)	Capsules: 250 mg. Syrup: 125 mg./5 ml.
Nystatin (Mycostatin)	Infants: 400,000-800,000 units/24 hours Children: 1-2 million units/24 hours Divide into 3 doses/24 hours (O) Oral moniliasis: t.i.d. (T)	Tablets: 0.5 million units Suspension (O or T): 100,000 units/ml.
Ouabain (g-Strophanthin)	0.010 mg./kg. 0.3 mg./M <sup>2</sup> ½ dose stat (I.V.) Then fractions of dose every 30 minutes until response or total dose is given (I.V.) Redigitalize with long-acting drug 12 hours after onset of treatment Check patient and EKG before each dose CAUTION: Not to be given if a digitalis type of drug has been given in preceding 2 weeks	Ampules: 0.25 mg./ml.

Table 43. Drugs and Drug Doses (*continued*)

<i>Drug</i>	<i>Dose</i>	<i>Supplied</i>
Pancreatin (Viokase, Panteric Granules)	Tablets: 1-2 tablets crushed with meals (O) Granules: $\frac{1}{4}$ - $\frac{1}{2}$ teaspoonful with meals (O) Gauge dose by quality of stools	Tablets: 0.3 gm. Granules: 1 and 4 oz. Powder
Papaverine	6 mg./kg./24 hours 200 mg./M <sup>2</sup> /24 hours Divide into 4 doses/24 hours (I.V. or I.M.)	Tablets: 30, 100 and 200 mg. Ampules: 30 mg./ml.
Para-aminosalicylic acid or salts (PAS)	200-400 mg./kg./24 hours 7.0 gm./M <sup>2</sup> /24 hours Divide into 3-4 doses/24 hours (O)	Tablets: 0.5 gm. Crystals: 0.5 gm.
Paradione (Paramethadione)	Under age 2 years: 0.3 gm./24 hours 2-6 years: 0.6 gm./24 hours Over 6 years and adults: 0.9 gm./24 hours Adjust subsequent doses by response (O) CAUTION: Blood dyscrasias	Capsules: 150 and 300 mg. Solution: 300 mg./ml.
Paraldehyde	0.15 ml./kg./dose 6.0 ml./M <sup>2</sup> /dose (O, R, I.M. or I.V. SLOWLY)	U.S.P. (Liquid)
Paregoric (Camphorated tincture of opium) (0.4 mg. of morphine/ml.)	Analgesic dose: 0.25-0.5 ml./kg./dose Smaller dose may be offered initially; increase to above as maximum Accurately measured with calibrated dropper (O)	U.S.P. tincture
Penicillin (aqueous) (1667 units/mg.)  (Procaine)	Infants: 20,000-50,000 units/kg./24 hours Older children: 300,000-600,000 units/24 hours Divided doses every 3-6 hours/day (O, I.M. or S.C.)  0.5-1.0 million units/M <sup>2</sup> /24 hours Single dose (I.M.)	Many forms and preparations
Penicillin benzathine (Bicillin, Permapen)	0.6-1.2 million units/dose at 24-72 hour intervals (I.M.) Rheumatic fever prophylaxis: 1-2 times/month	600,000 units/ml.
Penicillin V (1667 units/mg.)	100,000-300,000 units 4-5 times/day (O)	Many forms
Pentobarbital sodium (Nembutal)	Same as Phenobarbital	Same as Nembutal

Key: M<sup>2</sup>, dose per square meter of body surface.  
I.M., intramuscular.  
I.Th., intrathecal.  
I.V., intravenous.

O, oral.  
R, rectal.  
S.C., subcutaneous.  
T, topical.

Table 43. Drugs and Drug Doses (*continued*)

<i>Drug</i>	<i>Dose</i>	<i>Supplied</i>
Phenergan Hydrochloride (Promethazine hydrochloride)	0.5 mg./kg./dose 15 mg./M <sup>2</sup> /dose (O, R or I.M.) Antihistaminic: Full dose at night, $\frac{1}{4}$ dose A.M. or p.r.n. Nausea and vomiting: $\frac{1}{2}$ to full dose every 4-6 hours Preoperative: Full or double dose Motion sickness: Full dose, repeat 12 hours p.r.n.	Tablets (scored): 12.5 and 25 mg. Suppositories: 25 mg. Syrup: 6.25 mg./5 ml. Injection: 25 mg./ml.
Phenobarbital (Luminal)	Sedation: 6 mg./kg./24 hours 180 mg./M <sup>2</sup> /24 hours Divide into 3 doses (O, R, or I.M.) Anticonvulsant: 3-5 mg./kg./dose (I.M.) 125 mg./M <sup>2</sup> /dose (I.M.) Maximum dose, 300 mg.	Tablets: 15, 30 and 100 mg. Spansules: 60 and 100 mg. Elixir: 15 mg./5 ml. Ampules: 125 mg./2 grains 300 mg./5 grains
Picrotoxin	Barbiturate poisoning: 5 mg. (I.V. or I.M.) Repeat every 15 minutes	Ampules: 3 mg./ml.
Piperazine (as salts)	Pinworms: Up to 15 pounds: 250 mg. 15-30 pounds: 500 mg. 30-60 pounds: 1.0 gm. Over 60 pounds: 2.0 gm. 1.0 gm./M <sup>2</sup> Once daily before breakfast for 7 consecutive days (O) Roundworms: Up to 30 pounds: 1.0 gm. 30-50 pounds: 2.0 gm. 50-100 pounds: 3.0 gm. Over 100 pounds: 3.5 gm. 2.0 gm./M <sup>2</sup> Once daily for 2 consecutive days (O)	Tablets: 250 and 500 mg. Wafers: 500 mg. Syrup: 500 mg./5 ml.
Pitressin (Vasopressin)	Aqueous: 1-3 ml. (S.C.) Divide into 3 doses Tannate in Oil: 0.2 ml./dose (I.M.) Increase to 1-2 ml. 0.25-0.5 ml./M <sup>2</sup> (I.M.) Daily, twice daily or every other day (p.r.n.)	Vasopressin injection, U.S.P.: Aqueous: 20 units/ml. Pitressin Tannate in Oil: 5 units/ml.
Polymyxin B sulfate	Enteric infections: 10-20 mg./kg./24 hours 500 mg./M <sup>2</sup> /24 hours Divide into 3-4 doses/24 hours (O) Systemic infections: 1.5-2.5 mg./kg./24 hours (I.M.) 60 mg./M <sup>2</sup> /24 hours CAUTION: Nephrotoxic, neurotoxic	Tablets: 50 mg. Sterile powder: 50 mg./vial
Posterior Pituitary	Diabetes insipidus: Nasal insufflation p.r.n. (T)	Capsules of powder: 40 mg.

*ext continued from page 209)*

Liquid preparations are preferable for children under five years of age. They may be made with pleasant vehicles such as syrup of chocolate, cinnamon or lemon. The amount of alcohol in elixirs and some other liquid preparations need usually cause no concern.

Although solid medications are usually taken poorly by children under five years of age, toddlers, when left alone, ironically imitate themselves with swallowed tablets or other solids. The risk of aspiration from the forced administration of tablets or capsules is great; they are usually safe for children five years or older. If the patient objects, tablets may be crushed or capsule contents emptied and added to syrups, jellies, Jello applesauce. One should, however, generally avoid adding drugs to the formula or to a favorite food.

**The Sublingual Route.** Older children will often hold drugs in their mouths long enough for absorption directly into the systemic circulation, thus avoiding passage of the drug through the portal system and the liver, where much of a drug may be lost.

**The Rectal Route.** One cannot expect uniform results from rectal administrations. If the ampulla is full, a capsule, tablet or suppository may soon be discharged with the stool. A cleansing, nonirritating saline enema

given prior to the medication offers the best chance of absorption. Suppositories which melt at body temperature are more effective than those which depend upon solution for their action.

Drugs in liquid form may also be administered rectally. The drug should be dissolved or suspended in 10 to 30 ml. of fluid and injected into the rectum. The buttocks are held or taped to prevent expulsion.

Rectal therapy is ineffective in the presence of diarrhea or dehydration.

**The Parenteral Route.** No child looks forward to a "needle," but the parenteral route is often preferable for the treatment of severe or potentially severe illness, especially when vomiting precludes oral treatment. The speed of drug absorption by this route varies with (1) the tissue injected, (2) the absorbability of the drug or vehicle, and (3) the adequacy of circulation. Except in a few clearly stated instances, the contents of an ampule are not intended to be a single dose for a child.

A drug to be administered by some route not described above, as for example intradermally or topically, is so indicated in the discussion of the particular disease.

WILLIAM P. BARBA, II

## ANESTHESIA FOR CHILDREN

In order to provide adequate anesthesia for the pediatric patient, one must have (1) a working knowledge of the anatomic, physiologic and psychologic problems peculiar to the various age periods from birth to adolescence, (2) a thorough understanding of the surgical problem in each situation, (3) the ability to prescribe and evaluate fluid and electrolyte therapy, and (4) complete familiarity with the principles and techniques of sedation and of anesthesiology.

### PREOPERATIVE EVALUATION

Preparation for anesthesia begins with a detailed history, which should include information about previous anesthetic experiences and reactions to such drugs as barbiturates, opiates and derivatives of belladonna, and regional anesthetic agents such as procaine and pontocaine. It is also essential to know whether the child has recently had therapy with any

drug which might alter his response to sedatives and anesthetic agents as, for example, with the steroid hormones, anticonvulsant or tranquilizing drugs, antihypertensive agents or cardiac stimulants. Knowledge of previous transfusion or serum reactions or of prolonged bleeding or easy bruising may serve to forewarn of an otherwise unexpected complication. If there is any indication of an abnormal bleeding tendency, appropriate laboratory studies must be obtained. Evaluation of the functional capacity of a child with known cardiac or respiratory disease is essential to an accurate evaluation of his ability to withstand anesthesia and operation. An upper respiratory tract infection within a period of two weeks may increase the likelihood of laryngeal and tracheal complications. Recent loss of weight or failure of an adequate gain in weight may alter the expected response to sedative and anesthetic agents. Hypothyroidism or hyper-

thyroidism, adrenal insufficiency, diabetes mellitus and myasthenia gravis are examples of diseases which should alter the management during anesthesia and during the preoperative and postoperative periods.

A hemoglobin determination, a white blood cell count and a urinalysis constitute the minimal laboratory data which must be obtained within twenty-four hours of a procedure.

#### PREOPERATIVE PREPARATION

**Psychologic Aspects.** Children are frightened by leaving the security and familiarity of home and going to a strange hospital. Not knowing what to expect or on whom to call for assistance and sympathy generates fear and anxiety. The greatest incidence of psychic trauma following hospitalization is said to occur in infants and children one to three years of age, since they are unable to understand the purpose of hospitalization and do not realize that they can soon return home. Beyond this age there is increasing comprehension when the child is properly and adequately prepared for his hospitalization. Gross changes in the child's personality may follow traumatic emotional experiences.

A detailed description of what to expect is unnecessary. The child should know the general purpose of the proposed operation. If special equipment, such as an oxygen tent, is contemplated postoperatively, it is wise to introduce him to it a day before the operation so that he may "practice" with it and become accustomed to it. The unexpected should be avoided, if at all possible. No "white lies" should be told, but rather he should know that a certain amount of discomfort is necessary in order to get well.

Preparation for an elective operation should include a visit to the hospital a day or so before the scheduled admission in order that the child may become familiar with its appearance and with the principal personnel who will care for him. Children sense the tension and apprehension of parents and will reflect these attitudes; thus the parents must display confidence and cheerfulness. The child should bring a favorite toy or blanket to the hospital in order to alleviate some of the strangeness of his new environment. Every effort should be made by the surgeon and the child's physician to instruct the parents in preparation of the child emotionally before admission to the hospital. If the operation is a disfiguring one, such as an amputation or

the creation of a permanent colostomy, a psychiatrist or other physician, familiar with the problems of children, should assist in preparation of the child and his parents before operation. The anesthesiologist should visit the child, if possible in the presence of the parents, so that he will understand that the anesthesiologist is a friend who will care for him during the operation.

The immediate postoperative period is one of great emotional strain for the child; if possible, the parents should be with him to comfort and reassure him. Liberal visiting hours for parents should be encouraged as long as they do not seriously interfere with the hospital routine.

**General Medical Aspects.** Any acidosis, alkalosis, dehydration or hyperpyrexia must be corrected before induction of anesthesia to avoid precipitation of convulsions. Even emergency operation is rarely so urgent that time cannot be taken to improve the child's condition. For a major surgical procedure an intravenous infusion should be operating prior to induction of anesthesia, so that a means of administering blood, plasma or appropriate electrolyte solutions before and during operation is available. Hyperpyrexia may be lowered by external methods of cooling and by rectal administration of aspirin. In the presence of an acute infection necessitating a surgical procedure the temperature should not exceed 101° F. rectally, and the pulse rate should not exceed 120 per minute at the time anesthesia is begun. Cooling should be continued during anesthesia, if necessary, until a normal temperature is approached. Dehydration and abnormal concentrations of plasma electrolytes should be corrected by administration of appropriate fluids, which should also contain glucose (see p. 186).

A hemoglobin level of less than 10 gm. per 100 ml. is indicative of anemia, and elective operation should be postponed until it has been corrected. When the anemia is the result of recent rapid loss of blood, transfusion of whole blood is indicated, but only rarely is it indicated for an elective surgical procedure.

Obstruction of the respiratory tract by aspiration of regurgitated food during general anesthesia and in the immediate postoperative period is a major hazard. Solid food and milk should be withheld from all children for eight hours before induction of anesthesia; clear liquids to which additional sugar has

en added may be given within four hours; s is particularly important for small in- ts, and especially during hot weather. When the operation involves manipulation the upper gastrointestinal tract, a Levin be should be placed in the stomach before uction of anesthesia as a safeguard against gurgitation and aspiration of material into e tracheobronchial tree.

**Preanesthetic Medication.** Ideally, the pa- nt should arrive in the operating suite in rowsy, tranquil state. Quiescence is accom- shed by psychologic preparation and by the e of narcotic or sedative drugs.

Preanesthetic drugs (sedatives, narcotics d belladonna derivatives) are administered (1) to allay fear and apprehension, (2) to ecrease secretions from the respiratory tract, (3) to decrease the amounts of anesthetic gents required, and (4) to decrease unde- rable reflex activity, especially that of para- mpathetic origin.

Barbiturates allay apprehension more effec- tively than opiates (Dripps and Beecher). atients who receive short-acting barbiturates, uch as secobarbital or pentobarbital, pre- peratively will also awaken more quickly om general anesthesia and will regain their rojective pharyngeal and cough reflexes more apidly. This is particularly important for ndoral surgery, such as tonsillectomy or den- al procedures, in order to minimize aspiration f blood or secretions during the immediate ostoperative period. Barbiturates are classi- ed according to the duration of their action nd to their modes of inactivation and excre- tion. Pentobarbital and secobarbital are inacti- vated chiefly by the liver and have a relatively hort action; they should not be prescribed if here is hepatic damage. Phenobarbital and

barbital are long-acting barbiturates and are excreted by the kidneys. Thus the choice of the proper barbiturate depends on renal and hepatic function as well as on the duration of action desired. If a child has been receiving a barbiturate or other drug as an anticonvul- sant, it should be continued, and the usual preoperative medication should be prescribed in addition.

The narcotic drugs most commonly used for preoperative medication are morphine, meperidine (Demerol) and alphaprodine (Nisentil). There are four prime indications for their use: (1) for analgesia, (2) to lower oxygen requirements in the child with cya- notic heart disease, (3) for additional seda- tion and euphoria when operation is to be performed with regional analgesia, and (4) for intrathoracic surgery. Morphine is more effective than the other narcotics, but, in gen- eral, is more likely to cause nausea, vomiting and respiratory and circulatory depression.

The belladonna alkaloids used before oper- ation are atropine and scopolamine. Their purpose is to reduce secretions within the respiratory tract and to minimize undesirable autonomic reflexes. Scopolamine, when com- bined with a narcotic or barbiturate, produces a desirable degree of amnesia, and is a more effective drying agent than atropine. Atropine is superior for its protective action on cardiac and bronchial reflexes. Overdoses of either drug may cause hyperpyrexia, especially in the presence of even mild dehydration or in a hot, humid environment; Negroes require slightly larger doses, owing to their tendency to form excessive secretions. Scopolamine may cause agitation, and for this reason the dose is slightly smaller than that of atropine.

The anesthetist should refrain from using

Table 44. Preanesthetic Medication for Infants and Children

Age	Weight (Lbs.)	Nembutal (Mg.)	Morphine (Mg.)	Demerol (Mg.)	Atropine (Mg.)	Scopolamine (Mg.)
1 day-3 months.....	5-10	—	0.5-1	—	0.05-0.1	—
3-6 months.....	10-20	15-30	1-2	—	0.1-0.12	—

6-12 years.....	60-100	90-150	6-10	40-75	0.3-0.4	0.24-0.32
12+.....	100+	150-200	10	75-100	0.4-0.6	0.32-0.43

All drugs are given by the intramuscular route.

Nembutal is available in solution in multiple-dose vials containing 50 mg. per ml.

Scopolamine is available in ampules containing 0.32 or 0.43 mg. per ml.

Morphine should be prepared in solutions containing 4 mg. in each ml.

Average doses: Morphine, 0.1 mg. per lb.; Nembutal, 1.5 mg. per lb.; Demerol, 0.75 mg. per lb. These doses must be modified by certain conditions such as anemia, dehydration, malnutrition, asthma and drug sensitivity.

Approximately twice the foregoing doses can be given on basis of mg./kg. body weight.

any drug during anesthesia whose action is not thoroughly familiar to him. Weight is the most satisfactory basis for determining the dose for the average child; however, in special instances surface area and the metabolic activity of the patient must be considered. Narcotics such as morphine and Demerol should be prepared in dilute solutions to minimize errors in calculating the prescribed dose. The intramuscular route of administration is preferred.

The usual practice is to combine a barbiturate or an opiate with one of the belladonna derivatives; a particularly apprehensive child may be given all three drugs. They are administered sixty to ninety minutes before induction of anesthesia in the doses listed in Table 44.

INDUCTION OF ANESTHESIA

Induction of anesthesia in children should be accomplished with a minimum of crying and struggling and without the need for forcible restraint. With proper preanesthetic preparation it is usually possible to induce anesthesia by allowing cyclopropane or nitrous oxide to flow over the face by gravity. Conversation about subjects dear to the heart of the child will often serve to distract him during the early phase of induction. When the patient comes to the operating room with an intravenous infusion apparatus in place, induction may be accomplished with small doses of sodium pentothal injected directly into the tubing. Only when the child is completely unconscious is the mask slowly lowered and

fitted to the face. Anesthesia may then proceed by any desired method.

PHYSIOLOGIC CONSIDERATIONS DURING ANESTHESIA

Table 45 summarizes some of the data relative to the respiratory and circulatory systems which are useful to the anesthesiologist.

The circulatory system of infants and children is vulnerable to minute stresses and reacts vigorously and rapidly to them. The pulse rate in anesthetized infants varies between 80 and 180 per minute. A cardiac rate below 80 per minute in a young infant must be regarded as bradycardia and as a sign of impending hypoxia. The oxygen consumption of a newborn infant is approximately 7 ml. per kilogram per minute and is often higher in children one to three years of age. Owing to this high metabolic rate, even minor degrees of hypoxia are poorly tolerated.

Less often, bradycardia during general anesthesia is of autonomic reflex origin, frequently precipitated by a surgical stimulus, such as traction on the viscera. If the stimulus is released, the pulse rate usually returns to its previous level. Atropine, intravenously, will also often abolish bradycardia of parasympathetic origin.

The child not uncommonly has a slight lowering of blood pressure after moderate or heavy preoperative sedation; it is no cause for concern if he appears well otherwise.

The blood volume of a newborn infant is 400 to 500 ml., or 7.5 to 8.5 per cent of body weight. The loss of 30 ml. of blood by

From R. Dripps, J. E. Eckenhoff and L. D. Vandam: Introduction to Anesthesia, The Principles of Safe Practice.  
\* Data of Margery VanN. Deming, M.D.  
† O.D. = Outside Diameter.

six-months old infant is estimated to be equivalent to a loss of 500 ml. by an adult. It is essential to estimate the loss of blood during a major operation and to be prepared to replace any significant loss, volume for volume.

Owing to the relatively large surface area of infants and young children, and the immaturity of their neural heat regulatory mechanism, it is often difficult to control their temperatures. It is not uncommon for the temperature of a small infant to fall to 94° after a two- or three-hour surgical procedure in which a nonbreathing anesthetic technique is used. It is undesirable, however, to have the body temperature rise above normal, since this increases oxygen requirements. External warming and cooling devices should be used judiciously to keep the child's temperature 1 to 2 degrees below normal.

Generalized convulsions occur more frequently under general anesthesia in children than in adults. The factors which predispose to convulsions are hypoxia, hyperthermia, dehydration, disturbances of acid-base equilibrium, overdoses of atropine and scopolamine and certain anesthetic agents. Immediate therapy of a convulsion is aimed at preventing permanent cerebral damage by avoiding or correcting hypoxia and by stopping the seizure. Oxygen should be administered through a patent airway, with endotracheal intubation when necessary, and rapidly acting barbiturate administered intravenously to control the seizure. The surgical procedure should be terminated, and the factor responsible for the convulsion corrected before anesthesia is administered again.

The safety of any anesthetic procedure depends largely on the training, skill and experience of the anesthesiologist. Unless the surgical requirements demand a specific method of anesthesia, the simplest technique should be used by the anesthetist of limited

experience. Generally, the choice of anesthetic agents and methods of administration will depend on the anesthetist's ability, the seriousness of the child's illness and the contemplated operative procedure.

**FLUID THERAPY** (See page 183)

### POSTOPERATIVE CARE

The immediate postoperative period is a critical one; a "recovery room" adjacent to the operating suite should be available for observation of the child during this time. Nurses specially trained to observe postoperative patients for signs of respiratory obstruction, circulatory failure, silent regurgitation and other emergencies should be assigned to this unit, which contains equipment for suctioning, resuscitation, transfusions and other emergency measures. Members of the anesthesia and surgical staffs should be available for any necessary consultation and assistance. The child should leave the recovery area and return to his own room only after he has reacted adequately from anesthesia, when his pulse rate and blood pressure are stable, there is no respiratory depression, and the pharyngeal and cough reflexes are active.

In respiratory disturbances, particularly following endotracheal anesthesia in young children, breathing is facilitated by humidification of the environmental air, with oxygen added when necessary.

JACOB FRIEDMANN

## CONVALESCENT CARE

Convalescent care as a phase of medical responsibility in the management of the sick child is often overlooked. Its importance in certain diseases, notably rheumatic fever and crippling orthopedic conditions, is generally recognized, but the average busy practitioner gives little consideration to the completion of the recovery process in his patients. When the

active phase of an acute illness or an acute exacerbation of a chronic one has passed, the patient is likely to be dismissed with indefinite instructions to take things easy for a few days.

Literally, the term "convalesce" means to grow or become strong; in common usage it implies to recover from illness, to become well

or healthy again. Childhood is the period of rapid growth and development; no definition is sufficient which does not take these factors into consideration. Perhaps a more adequate definition would be the attainment of optimal physical, mental and social health after illness. Such a connotation has the advantage that the recovery level is gauged by the delimiting factors of the individual child and his increasing age. A child with no physical residuals would thus be expected to attain a state of robust health in contrast to a child with a damaged myocardium from a rheumatic lesion who might have sufficient permanent damage that his state of optimal health would be at a lower level. Such a concept is important, not only for the sake of setting the goal for each child, whenever possible, at a level higher than that of the pre-illness state, but also to determine, as accurately as possible, for the handicapped child the limits of his capacity. The physician must also be aware that illness may interfere with the normal development of the mental and social status of the child. Convalescence cannot be considered complete unless the child has also attained his optimal mental and social levels.

In a broad sense, any child who is below par physically is in need of convalescent care. In a stricter and perhaps more practical sense the term "convalescent care" should be reserved for the management of the more serious deviations from states of health which are the result of an acute or chronic illness, and for which at least some degree of improvement can be expected.

Convalescence from short-term acute illnesses in previously healthy children should be completed in a relatively short time, not longer than that of the acute stage of the illness. In such instances gradual increases in activity with special attention to essential factors in the diet are usually all that is required. When the illness has been prolonged or unusually severe, greater attention is necessary.

The care of the convalescent child should be designed to follow natural patterns as far as possible. The principal factors are (1) provision for adequate rest; (2) increasing but graded physical activity; (3) diets which take into account increased need for such essential items as protein, vitamins and minerals; (4) play and occupational therapy; (5) continuation of formal schooling by the visiting teacher in the private home or by a resident teacher in institutions; and (6) an environment which stimulates self-confidence

in the child and at the same time provides an adequate sense of security. Though the child should be managed in such a way that he does not have a sense of self-pity, attempts at developing the Spartan attitude are often overdone. A fine degree of understanding is necessary to guide the child who requires a long period of convalescence.

Rest is perhaps the most efficient tool for repairing the ravages of disease, yet we know all too little of its quantitative administration. Those who have worked in the recovery wards of hospitals or in convalescent homes, or have observed convalescent children in their own homes, have noted the extreme degrees of restlessness and even of unhappiness in children whose activity was limited beyond what appeared to be their natural desires, especially when there was inadequate provision for occupational and play therapy. Paradoxical as it may seem, physical activity may at times be reduced by permitting greater latitude in movement. The restless child may expend more energy in continuous activity in bed than he would if allowed short periods out of bed. In the evaluation of the benefits to be derived from rest, such general but diametrically opposed concepts as recovery of structure and function with rest and the atrophy or disuse must be considered. Retention of calcium and nitrogen during periods of enforced inactivity may be less than on corresponding intakes during states of normal activity, and there may even be negative balances on otherwise adequate dietary intakes.

A workable plan for grading activity from bed rest to full activity is as follows: When the temperature is normal and other evidences of infection have subsided, the child should be allowed some activity, provided there is no residual damage which requires special consideration, such as cardiac damage from rheumatic fever or crippling orthopedic conditions. When there is no evidence of fatigue, the child may be permitted to sit for increasing periods of time at a table or window or on a porch to provide changes in activity or view. Bathroom privileges can usually be allowed as soon as the child is out of bed, and dining room privileges within another day or two. Otherwise, until there is a good return of physical strength, activity should be limited to the child's room or to the porch or terrace in suitable weather. Exposure to the sun should be encouraged so long as burning is avoided. The next increase in activity may include walking, croquet and playing catch with a ball. After this stage full activity

permitted. The rate at which activity is increased depends on the child's response. So long as additions do not cause a loss in weight and are below the fatigue level, they may be considered safe. Evidences of fatigue will be reflected by facial appearance, body posture and emotional responses. When an increase in activity is not well tolerated, it should be reduced to a lower level until the child again seems ready for greater activity.

Rheumatic fever patients with cardiac involvement require special consideration (p. 13). Besides the general criteria for determining the times for starting and increasing activity, attention must also be given to the possibility of continued infection as measured by the sedimentation rate and to the possibility of cardiac decompensation. The size of the heart, the pulse rate at rest and after exercise, the temperature curve uninfluenced by salicylates, and the general response to exercise must be evaluated. Some children with residual cardiac damage will never be able to tolerate full physical activity, and it is of the greatest importance to determine the upper level of activity compatible with their cardiac capacity and to inform them and their parents of their physical limitations.

The convalescent care of orthopedic patients must be governed by their physical limitations; they should have the benefit of expert supervision.

Children in need of convalescent care simply because of nutritional deficiency present special problems, particularly in subsequent home care if the convalescent period has been spent in an institution. If the undernutrition has been due to economic factors, every effort should be made to see that ample food supplies are available. When the undernutrition has resulted from poor eating habits, which frequently are due to poor training and disturbed parent-child relationships, reconstructive work must be carried on with the parents as well as the child.

The private home can usually be adjusted for short-term convalescent periods, but is only adequate for a long time when the family is capable of making the necessary adjust-

ments. Foster homes, if adequately supervised, can be of great benefit when the child's own home is inadequate. They are also safer places than large institutions for children under the age of two or three years, owing to the high susceptibility to respiratory infections during infancy and early childhood.

Properly conducted convalescent homes have proved their worth for children who require a long period of convalescence. They have the advantage that the child is in contact with other children whose problems are similar and thus require similar methods for their solution. Institutions, however, cannot provide adequate substitutes for family living, and even the best of them can to advantage be integrated with a home-care program. In such a plan the child who requires prolonged convalescence would spend alternate periods at the convalescent home and in his own home. General convalescent homes may also serve a useful function in providing a place of recuperation for children in need of mental rest and psychologic adjustment because of disturbed situations within their own homes. Such institutions are adequate, however, only so far as they satisfy the physical, mental, social, educational and religious demands of the individual child.

In most areas there are either inadequate or no facilities for institutional convalescent care for children, so that the responsibility for supervision of long convalescence within the child's own home falls upon the physician. If he assumes this responsibility, he must recognize that he must provide for the whole child. He will do well to enlist the aid of persons who can provide play and occupational therapy and schooling within limits which stimulate but do not overtax the child. In some instances the mother may be adequate for this task; in others, dependence will have to be placed upon such persons as visiting teachers and visiting nurses. Communities which do not have convalescent institutions could with advantage organize such home-care service for convalescent patients.

# Prenatal Disturbances

## PRENATAL FACTORS IN DISEASES OF CHILDREN

### GENETIC AND ENVIRONMENTAL FACTORS

The interplay of many factors determines health or disease of children. The physician who observes many persons exposed to equal traumas, infections or deficiencies notices that they react differently to injuries of the same type and intensity. Such differences are conveniently explained as due to varying "constitutions." It may be useful to attempt an analysis of latent or remote factors underlying this differential behavior. Some of these factors were at work before the child was born, and obviously it is difficult to study them. However, the remoteness or latency of these factors does not make them less real, and they deserve as much study and, if possible, treatment as the factors which finally elicit the disease.

**The Fertilized Ovum.** The child's life begins with fertilization of the ovum. The structure and composition of the fertilized egg (zygote) determine the somatic and mental traits of the new individual, but a favorable environment is also indispensable for coordinated embryonic differentiation and intrauterine growth. Abnormalities of the elements of the zygote as well as prenatal environmental disturbances may result in congenital defects or the formation of points of minor resistance in the new organism. Congenital deviations are often at the root of chronic and intractable diseases of children.

The fertilized ovum consists of the cytoplasm and the nuclear substance. The latter contains the chromosomes and their constituents, the genes. The structure of the cytoplasm is of great importance for the development of the embryo; abnormalities of the cytoplasm apparently may lead to such severe impairment that the resulting embryos seldom reach postnatal life. Abnormalities of the chromosomes and genes cause many defects

encountered in children. In addition, injurious environmental factors are capable of altering the development of an otherwise healthy zygote and are thus responsible for the production of abnormalities. Such factors should be more accessible to preventive measures than other prenatal pathogenic factors.

**Injurious Factors.** Injurious genetic and prenatal environmental factors will be discussed separately, although they are difficult to distinguish in practice. Prenatal development is regulated by a continuous interaction of genes with their surrounding cytoplasm, the latter reacting in turn with the intramaterial and extramaterial environments. This continuous process may be regarded as a chain of complicated physical and chemical reactions, which may be interrupted by genetic as well as by environmental interference. The end result of different disturbing influences may be the same. Genetically determined abnormalities may be imitated by environmental disturbances and result in nonhereditary "phenocopies" of hereditary defects.

### GENETIC FACTORS

In man the nuclear substance of the zygote and of all the somatic cells derived from it contains forty-eight chromosomes, the carriers of the genes.\* The germ cells (gametes) contain only half the number of chromosomes. The union of two gametes, sperm and ovum, re-establishes in the fertilized ovum the number of chromosomes characteristic for the somatic cells of the species. Thus twenty-four of the forty-eight chromosomes of each cell can be traced back to the paternal and twenty-four to the maternal germ cells. The paternal as well as the maternal series of chromosomes

\* Until recently it was thought that man has forty-eight chromosomes, but more accurate counts have established the normal number as forty-six.

contains a complete assortment of genes and therefore a complete set of developmental potentialities. With the exception of the sex chromosomes, the paternal and maternal chromosomes resemble each other so closely that they can be grouped in twenty-three homologous pairs containing twenty-three homologous sets of genes. Thus every hereditary trait is determined by a pair or several pairs of genes. In general, the members of a pair of genes have a similar principal function: They regulate some phase of the development of the same organ or system. They may differ somewhat in their qualitative or quantitative potentialities, or may be identical. A person who carries a pair of genes which tend to produce identical results is considered *homozygous* for the trait they determine. If the two members of the pair tend to produce somewhat different results, the person is *heterozygous*. In that case one of the genes usually assumes leadership, and the other fails to express itself. The stronger gene is called "dominant," the suppressed one, "recessive." Though a recessive gene cannot express itself in a heterozygous person, it can act if united with an equivalent recessive gene in a homozygous person.

The dominant genes usually determine the traits of heterozygous persons. Since the recessive genes are not expressed in heterozygous persons, the appearance, or *phenotype*, of such persons differs from their genetic constitution, or *genotype*.

A reduction division precedes formation of the germ cells. The members of each chromosome pair separate, and only one member of the pair enters the final germ cell. Therefore each germ cell contains twenty-four (twenty-four?) chromosomes. It is a matter of chance whether it is the maternal or paternal member of the pair that is included in a germ cell. Thus any one germ cell will contain a mixture of maternal and paternal chromosomes, and all possible combinations may occur by the laws of chance. Though the chromosomes dissociate and segregate freely, certain genes are linked by their common location on the same chromosome and tend to remain together in inheritance.

A few types of morbid inheritance will be cited as examples of prenatal factors in the etiology of diseases of children. No attempt will be made to simplify a complicated subject. For more complete details of normal and morbid inheritance, the reader is referred to the literature cited.

### DOMINANT PATHOLOGIC TRAITS\*

A person who has a dominant abnormal trait is usually heterozygous. Such a person has one dominant, pathologic gene ( $P$ ) and one recessive, normal gene ( $p$ ) for the trait in question. The person shows the pathologic trait, since the abnormal gene expresses itself, and the action of the normal one is suppressed. Such a person ( $Pp$ ) usually marries a person who is free of the same pathologic trait and has two normal recessive genes ( $pp$ ) for the character in question. The abnormal person forms two kinds of germ cells in about equal numbers, those containing the gene  $P$  and others containing the gene  $p$ . All the germ cells of the normal mate contain the gene  $p$ . Figure 37 illustrates the results to be expected from such a mating: Half of the offspring ( $Pp$ ) can be expected to carry and exhibit the pathologic trait, but the other half ( $pp$ ) will be entirely free of it. A dominant abnormality appears in every generation of a kinship, and each offspring of an affected parent has an equal chance of being affected or unaffected. If one of these affected children marries a normal person, he must expect to see the trait in half of his offspring. However, those children who do not show the trait will have entirely normal offspring if their mates are normal.

Figure 38 presents a pedigree in which a pathologic trait, multiple exostoses, is inherited as a dominant factor. The abnormal trait is transmitted from affected parents to approximately half of their children, while the other members who are free of the trait have only healthy offspring. Ratios predicted from the type of diagram illustrated on page 237 actually occur in genetic experiments when large numbers of plants or animals are

\* Designations for genes (for the present discussion the following arbitrary symbols for genes are used):

#### Dominant Traits

$P$  = Dominant pathologic gene  
 $p$  = Recessive normal gene

#### Recessive Traits

$N$  = Dominant normal gene  
 $n$  = Recessive pathologic gene

FIG. 37

FIG. 38. Pedigree of a sibship in which multiple exostoses occurred in several members. The abnormal condition was transmitted by the affected members to part of their offspring, but the children of the unaffected members remained free. This suggests a dominant mode of inheritance. The pedigree was drawn according to the report of the mother of the propositus (↗), a 4-year-old patient of the Children's Hospital, Cincinnati, Ohio.

■ ● Persons with multiple exostoses.

▨ Man with a "bone disease" considered tuberculous (?).

See Figure 39 for explanation of other symbols.

crossed. In small human families, however, the actual ratio of normal to abnormal offspring may differ from the statistical expectancy, owing to random variation.

A number of pathologic conditions are inherited as dominant traits: multiple exostoses, osteopsathyrosis, coloboma iridis, aniridia, night blindness (without myopia), Huntington's chorea, neurofibromatosis (von Recklinghausen), spherocytosis and sickle anemia. In addition, certain forms of the following disorders may be inherited in a dominant manner: diabetes insipidus, brachydactyly, split hand, polydactyly, syndactyly, chondrodystrophy, microphthalmus, cataract, glioma retinae, optic atrophy, cerebellar ataxia, Friedreich's ataxia, hereditary spastic paraplegia, progressive muscular dystrophy, myotonia congenita, peroneal atrophy and epidermolysis bullosa. (See also Recessive Pathologic Traits, p. 238.)

*Inheritance of a pathologic trait in one or several pedigrees does not imply that the trait in question is always hereditary, nor that it is always inherited in the same manner.*

**Modification of Hereditary Traits. Skipping of a generation.** Contrary to the rule developed, a dominant trait may appear to skip a generation. Thus the abnormal trait may not be apparent in a person who has inherited the abnormal gene and transmits it to one half of his offspring. This behavior may be due to reduced *expressivity* of the gene, which may cause only a slight abnormality not obvious to the casual observer. In some instances the abnormality may be found in a mild form (microform). In some

cases of hereditary malformations, such as brachydactyly or exostoses, apparent skipping can be explained by roentgenographic demonstration of the abnormality in a mild form in an apparently normal parent who transmits the anomaly to some of his children. In other instances chemical or hematologic methods reveal that the transmitting person carries a basic hereditary anomaly (hyperuricemia in spherocytosis) without clinical manifestation (gout, hemolytic jaundice).

Breeding experiments often fail to produce the expected number of abnormal offspring, but since some of the phenotypically normal parents transmit the abnormal trait to some of their offspring, it must be assumed that the pathologic gene failed to manifest itself in the parents. Skipping of a generation in this manner is attributed to reduced *penetrance* (the percentual frequency with which a heterozygous dominant or a homozygous recessive gene manifests itself). Other genetic or environmental factors may be responsible for the varied expression of the abnormal trait.

**Environmental effects.** Environment plays an important role in the postnatal manifestation of hereditary diseases, in which only a "tendency" is genetically transmitted. The disease may be manifest in a person with the abnormal tendency only if he encounters certain environmental conditions. Thus tendencies to allergic conditions are inherited, but manifestations may be absent if exposure and sensitization to an allergen do not occur.

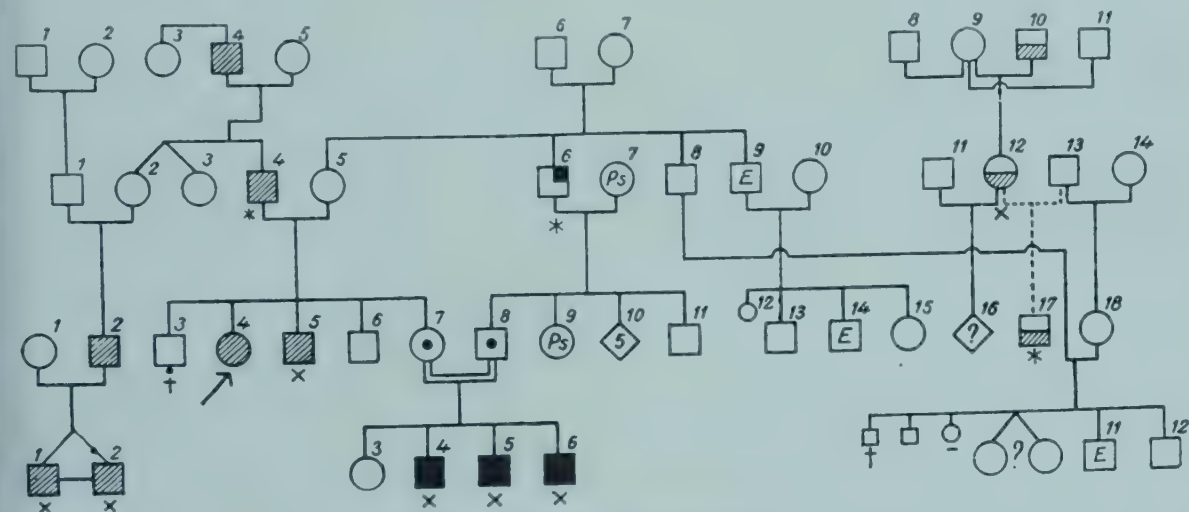

The basis for such pathologic tendencies may be anatomic, histologic or functional

ions from the normal which often are not manifest clinically. Thus unusual thickness of the red blood corpuscles (spherocytosis) may be observed in certain families as a dominant hereditary trait. Some carriers of spherocytosis are completely unaware of their abnormal trait, whereas in others there is an increased hemolysis of the abnormal cells, with resultant anemia, jaundice, splenomegaly and a variety of other clinical manifestations. The clinical patterns of those with the same disease vary markedly, and members of an affected family may have no symptoms in common. Thus spherocytosis, inherited as a simple dominant, may cause a confusing variety of clinical symptoms (pleiotropism), which may not be recognized as being related without hematologic studies. Patients with hemolytic jaundice can be freed of their disabling symptoms by splenectomy. This shows that a hereditary disease can be effectively

treated postnatally and refutes the false but widely accepted opinion that "nothing can be done about hereditary diseases." Splenectomy, however, does not change the patient's genetic make-up, and he can transmit the abnormal trait to half of his offspring.

Another example of multiple symptoms of one dominant hereditary trait is represented by a *mesenchymal dysplasia*, which manifests itself in bluish scleras and long, gracile bones. Such bones may fracture with the slightest trauma. Some affected persons have a tendency to dislocations of joints, some to otosclerosis. In taking a history of the sibship of an affected person one may learn that one member suffered from deafness and multiple dislocations, and other members were subject to multiple fractures (Fig. 40). Unless the observer knows the disease entity, he will not recognize the dominant inheritance of the underlying trait.

EXPLANATION OF SYMBOLS

Standard for all Pedigree-Charts:

- = Male
- = Female
- = Sex unknown
- = Sex unknown number unknown
- = 5 Children sex unknown
- x = tested by investigator himself
- \* = tested by other competent person (who?)
- = abortive male
- = premature male
- = deadborn male
- † = died in infancy
- ↗ = points to probandus
- = non identical twins
- = identical twins
- = twins uncertain if identical or not
- = carrier
- = parents
- = children
- = parents not married
- = illegitimate child
- = consanguineous marriage
- Roman figures to the left indicate generations in ascending and descending line
- Pr = generation of the probandus
- Arabic figures locate individuals (thus Pr 7 = the woman in the generation of the probandus who married her cousin. AII 9 = the woman in the second ascending generation who married 3 times (resp with AII 8 10 and 11)).

Especially devised or selected for this particular pedigree-chart:

- = polydactyly
- = deafmuteness
- = deafness
- Ps = psychopathic
- E = epileptic.
- = strongly curled hair
- Other symbols may be used and added.

FIG. 39. Standard symbols for pedigree charts. (Bureau of Human Heredity, London.)

■ ● Persons with blue sclerae.

FIG. 40. Pedigree of a family in which blue sclerae occurred in several members. In addition, the following associated symptoms were seen by the recorder or reported by a member of the family (II<sub>4</sub>): III<sub>1</sub>: long, gracile bones in roentgenograms; III<sub>2</sub>: multiple fractures (osteopsathyrosis); III<sub>6</sub>: multiple fractures; II<sub>1</sub>: multiple fractures; II<sub>4</sub>: multiple dislocations, otosclerosis.

The abnormal condition which manifested itself in various symptoms was transmitted as a dominant trait.

■ ● Persons with blue sclerae.

**Incompatibility of Parental Genetic Factors.** The degree of complexity with which genetic factors may interact with other factors in the etiology of disease is well-illustrated in erythroblastosis fetalis. In this condition the interaction of *normal* genes of the parents is associated with a pathologic condition in the fetus or newborn infant which stems directly from these normal genes.

Approximately 85 per cent of white persons of European origin carry on their red blood cells an antigen, the Rh<sub>o</sub> (D) factor, determined by a corresponding gene Rh<sub>o</sub> (D). These persons are designated "Rh positive" and appear as homozygous Rh positive (Rh Rh) or heterozygous Rh positive (Rh rh), according to whether the Rh gene was inherited from only one or from both parents. Persons lacking the gene are "Rh negative" (rh rh) and are homozygous.

Figure 41 shows how the three major Rh types can be formed in a family in which the parents are heterozygous and indicates that the relative frequencies of offspring in such families will be one Rh-positive homozygous and one Rh-negative person for each two heterozygous persons.

If transfusions of Rh-positive blood are made into Rh-negative persons, antibodies (agglutinins) to the Rh-positive red blood cell will usually develop. These antibodies may be the cause of transfusion reactions, or, in female recipients who later become pregnant with Rh-positive infants, the antibodies may cause hemolytic disease (erythroblastosis fetalis) in the infant as a result of their trans-

FIG. 41.

FIG. 42.

FIG. 43.

fer across the placenta. An Rh-negative mother who has *not* been transfused with Rh-positive blood may have infants with hemolytic disease after stimulation by red blood cells which cross into her circulation from an Rh-positive fetus. When maternal sensitization occurs as a result of pregnancy alone, the first child almost always escapes, but subsequent children. Once sensitization is established, however, subsequent Rh-positive children will usually have some degree of hemolytic disease. The tendency for the first child to be free of the disease is unlike a phenomenon seen with the action of ordinary dominant or recessive genes.

In an Rh-negative sensitized woman married to a homozygous Rh-positive husband all children will be Rh positive (Fig. 42) whereas, if the father is heterozygous, the children will have a 50 per cent chance to be Rh negative (Fig. 43).

#### RECESSIVE PATHOLOGIC TRAITS\*

A person with an abnormal recessive gene paired with a normal dominant gene appears normal and produces normal offspring with a mate who has two normal genes for the trait in question. If, however, such a heterozygous person marries a person who is similarly heterozygous, then each child has one chance in four of being homozygous and showing the pathologic trait. In Figure 44 the two apparently normal but actually heterozygous

\* See footnote, page 235.

ents are represented by  $(Nn)$ ,  $N$  representing the normal dominant and  $n$  the pathologic, recessive gene:

FIG. 44.

One abnormal offspring has the genetic constitution  $(nn)$ . Three fourths of the offspring appear phenotypically normal, but only one fourth  $(NN)$  is genotypically normal. One half of the children  $(Nn)$  are heterozygous, like the parents; they appear normal, but carry the pathologic gene. Since such carriers have one recessive abnormal gene appear normal, there is the possibility that they may carry unknowingly a carrier of the same pathologic trait. The chances of such a mating are related to the frequency of the pathologic gene in the general population. Consanguineous marriages favor the appearance of recessive traits. If a recessive gene is rare in a population, a homozygous, affected individual may appear only once in a pedigree. Thus the lack of a pathologic trait in the traceable genealogy does not exclude its genetic determination.

An interesting situation arises if a homozygous person with a pathologic trait caused by recessive genes  $(nn)$  marries an apparently normal person who is actually a heterozygous carrier of the same pathologic gene  $(Nn)$  (Fig. 46). In this case half of the

FIG. 46.

children appear normal and the other half exhibit the pathologic trait. To the observer such a family will appear like the one represented by the diagram on page 235, where an abnormal person, heterozygous for a dominant pathologic gene  $(Pp)$ , married a normal person  $(pp)$ . In both cases one of the parents and half of the children show the defect. But the genetic make-up of the children is different. In the case of the dominant pathologic trait the unaffected children are genetically entirely normal. They neither show nor carry the abnormal gene. In the case of the recessive abnormal character the children who appear normal carry the pathologic gene and transmit it to half of their children.

Thus a family history which includes only the parents and their children is insufficient to determine whether a pathologic trait is inherited as a dominant or a recessive one.

If two persons who exhibit an abnormal recessive trait and are therefore homozygous  $(nn)$  marry, the expectation is that all their offspring will be abnormal (Fig. 47). Such

FIG. 47.

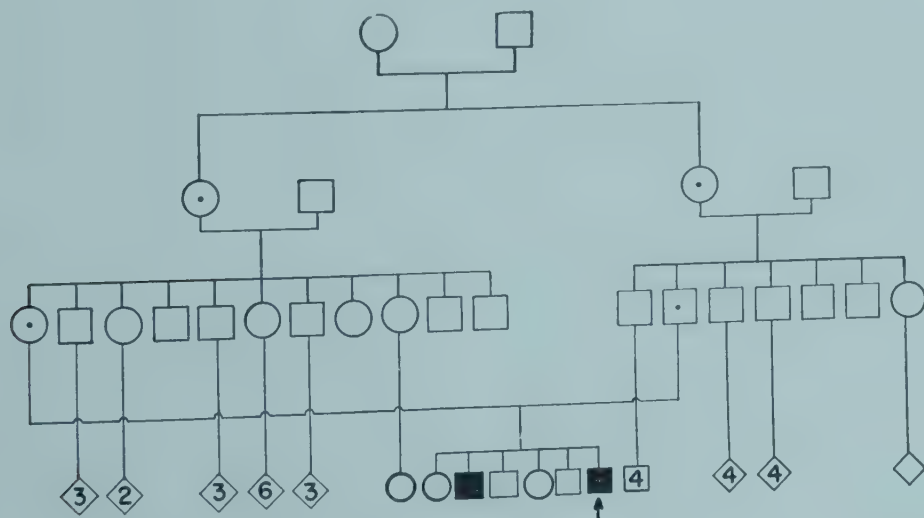

FIG. 45. Werdnig-Hoffmann muscular atrophy (■) occurring in offspring of a consanguineous marriage. The disease does not appear in the collateral close relatives, but because the recessive disease-producing gene has been received by both parents from one of their common ancestors, each of their offspring has one chance in four of being homozygous  $(nn)$  for it and developing the disease.

FIG. 48. Deaf-mutism (■ ●) in a pedigree recorded by Albrecht, inherited as a recessive trait. The deaf-mutism of all the affected persons is genetically determined with the exception of that of II<sub>3</sub>, who acquired deafness as a sequel of scarlet fever in infancy. (After Blacker.)

FIG. 49.

matings occur sometimes with deleterious effects among hereditary deaf-mutes. On the other hand, there is no objection to the marriage of persons whose deaf-mutism is acquired and not genetically determined. Figure 48 represents a pedigree in which two marriages of deaf-mutes occurred: II<sub>5</sub> and II<sub>6</sub> suffered from hereditary deaf-mutism, and all children were deaf-mutes. The marriage of II<sub>2</sub> and II<sub>3</sub> resulted in the birth of two normal children. Though II<sub>2</sub> was genetically a deaf-mute, II<sub>3</sub> was genetically normal and acquired deafness as a sequel of scarlet fever in infancy. Only normal children, all carriers of the pathologic trait, will be expected from such a marriage (Fig. 49). It is also possible that two deaf-mute persons who are affected by different genes for deaf-mutism may have normal children.

The following pathologic conditions are apparently inherited as recessive traits: albinism, Gaucher's disease, Tay-Sachs disease, Niemann-Pick disease, alcaptonuria and congenital ichthyosis. Certain forms of the following disorders can also be inherited as recessive traits: Fanconi's rachitic syndrome, polydactylism, atypical chondrodystrophy, Morquio's disease, gargoylism, osteopetrosis, microcephaly, microphthalmus, optic atrophy, cerebellar ataxia, Friedreich's ataxia, hereditary spastic paraplegia, progressive muscular dystrophy, peroneal atrophy, fibrocystic disease of the pancreas, galactosemia, phenylpyruvic oligophrenia, Wilson's disease, Laurence-Moon-Biedl syndrome and epidermolysis bullosa. (See also Dominant Pathologic Traits, p. 235.)

A number of clinical entities may be inherited as either dominant or recessive traits.

#### SEX-LINKED RECESSIVE PATHOLOGIC TRAITS

Of the forty-eight chromosomes of human cells, only forty-six can be arranged in twenty-three homologous pairs. The remaining pair, the sex chromosomes, requires special discussion. In males this pair consists of two chromosomes of unequal size: a large X chromosome and a small Y chromosome. In females there are two large X chromosomes. The every somatic cell of the male organism contains twenty-three pairs of homologous chromosomes (autosomes) plus one X and one Y chromosome, and every somatic cell of the female organism contains twenty-three pairs of autosomes and two X chromosomes. Meiosis, which leads to the formation of germ cells, produces two types of sperm cells: one containing twenty-three autosomes and a small Y chromosome and another containing twenty-three autosomes and a large X chromosome. All the germ cells produced by the male contain twenty-three autosomes and an X chromosome. Fertilization may result, therefore, in the formation of one of two types of zygotes: one which receives an X chromosome from both father and mother, the resulting offspring being female (XX), and another which receives a Y chromosome from the father and an X chromosome from the mother, the offspring being male (XY). The large X chromosome carries many genes, the small Y chromosome few, if any. Since most characters depend genetically upon the action of a pair of homologous chromosomes, the genes of the X chromosome of the male are in an exceptional position in this respect because they are not matched by corresponding genes of the Y chromosome. If a pathologic gene is located in the X chromosome of the male, it can manifest itself even if it is recessive, since it is not checked by a normal gene of the Y chromosome. A similar recessive pathologic gene in the X chromosome of a female may be kept in check, however, by a normal dominant gene in the other X chromosome. In this manner certain hereditary pathologic traits may appear in the males of a family without becoming manifest in females. Hemophilia, color blindness, some forms of gargoylism, progressive muscular dystrophy, peroneal atrophy, microphthalmus, night blindness with myopia, and the atrophic type of ectodermal dysplasia are sex-linked traits.

Figure 50 illustrates the transmission of

FIG. 50.

FIG. 51.

recessive pathologic gene located in an X chromosome ( $n_x$ ). There is no corresponding gene in the Y chromosome ( $O_Y$ ). The affected father's pair of genes is represented by the formula ( $n_x O_Y$ ). If the mother has two normal dominant genes in her X chromosomes ( $N_X N_X$ ), the following results are to be expected: The sons ( $N_X O_Y$ ) are all normal, having received their normal X chromosome from their mother. All the daughters ( $N_X n_x$ ) appear normal, but carry a recessive pathologic gene ( $n_x$ ) in one of their X chromosomes. If such a carrier-daughter marries a normal man ( $N_X O_Y$ ), half of her sons ( $n_x O_Y$ ) will show the abnormal trait of the paternal grandfather, and half will be genetically normal ( $N_X O_Y$ ). Half of the daughters will be genetically normal ( $N_X N_X$ ), and half ( $N_X n_x$ ) will carry the pathologic trait on one X chromosome (Fig. 51).

Figure 52 shows the sex-linked recessive inheritance of progressive muscular dystrophy in a sibship. This type of pathologic trait appears chiefly in males, but in rare cases females will also have it. If an affected

FIG. 53.

man ( $n_x O_Y$ ) marries a carrier ( $N_X n_x$ ), half their daughters ( $n_x n_x$ ) will have the disease and half will be carriers ( $N_X n_x$ ); half their sons will be affected ( $n_x O_Y$ ), and half will be genetically normal ( $N_X O_Y$ ) (Fig. 53).

PATHOLOGIC TRAITS WHICH DEPEND ON MULTIPLE GENETIC FACTORS

The hereditary traits discussed so far are attributable to one gene or one pair of genes. Hereditary characters may depend on the combined action of several genes, however. If these genes are located in different chromosomes, they associate and dissociate in different matings according to the laws of chance. Obviously the chances of the manifestation of a pathologic trait are diminished if it is dependent upon several genes. In simple recessive inheritance two genes of a pair determine the manifestation of a recessive trait. The chances that they unite in the offspring of a pair of carriers ( $Nn$ ) are 1 in 4. If a pathologic trait depends upon several pairs of recessive genes located in different chromosomes, the chances that they will become homozygous in one person are rather small. Thus the chances of the appearance of the trait are so diminished that one can expect to see it only rarely in a human pedigree. This illustrates again that the lack of a pathologic trait in the traceable genealogy does not exclude its genetic determination.

FIG. 52. Pedigree in which progressive pseudohypertrophic muscular dystrophy was transmitted as a sex-linked recessive trait. The pedigree was drawn according to the report of the mother of the proband (II-5), a 5 year old patient in the Children's Hospital, Cincinnati, Ohio.

The maternal grandmother of the patient was obviously a carrier of the abnormal trait, which was transmitted to 3 of her sons. A fourth son, who did not inherit the disorder to a part of their sons. Since this pedigree was drawn the daughter marked II-5 had 2 sons; both have progressive muscular dystrophy.

- Patients with progressive muscular dystrophy.
- ▨ Patient with a mild case of muscular dystrophy who recovered, according to the reporter.

### LETHAL TRAITS

A gene or a combination of genes may lead to developmental defects incompatible with life. Severe defects cause intrauterine death; the responsible genes are called "lethal genes." Milder defects may be compatible with intrauterine life, but cause death soon after birth; responsible genes are termed "sublethal."

Lethal genes may be dominant or recessive. They may produce only slight effects in heterozygous persons, but may cause death in the homozygote. For example, a dominant gene is known which, in heterozygous subjects, leads to brachyphalangia, a shortening of the second phalanx of the second fingers and toes. Such a defect is of no practical importance to the affected person. If, however, two heterozygous persons with this defect marry, one fourth of their offspring may be homozygous. Such a homozygous person may have no fingers and toes and have other osseous defects incompatible with normal postnatal life. This dominant gene is sublethal in homozygous persons.

Congenital ichthyosis may be cited as an example of a disorder which appears in children homozygous for a recessive sublethal gene. The parents of such children appear normal, but carry the abnormal gene, and some of their offspring present hyperkeratosis incompatible with life.

### ENVIRONMENTAL FACTORS

In mammals prenatal development is protected, since it takes place in the uterus, but this protection is not complete. Mechanical, actinic, chemical, nutritional and infectious agents may cause prenatal injury.

Intrauterine life may be divided into an *embryonic period* (approximately the first trimester) and a *fetal period* (from the twelfth week to birth). This division is arbitrary, but it distinguishes the period in which organogenesis takes place from the period which is chiefly devoted to growth. Severe injuries lead to prenatal death, but milder injuries may result in changes compatible with life. Environmental interference during the embryonic period leads to arrest of development and to malformations. A noxious agent may be harmless at certain stages of this period and deleterious at others, since the various organs are sensitive to noxious agents at periods of rapid differentiation and less sensitive to them in resting stages. It can be assumed that agents responsible for malformations act early in prenatal life, probably

within the first two or three months of gestation. Later, during the fetal period, injuries result in changes which more closely resemble those of postnatal damage, such as scars and mutilations.

**Mechanical Injuries.** Mechanical injuries may result in fetal death. External, intra-abdominal or intrauterine pressure has been said to lead to malformations, but only a few specific possibilities are seriously considered at present. In extrauterine pregnancies the fetus is often deformed. The deformity cannot be attributed to mechanical causes alone, however, since an ectopic embryo is embedded in an abnormal decidua, and faulty nutrition may be the cause. Malformations in a twin can in some instances be attributable to pressure exerted by the other twin. It is often asserted that intrauterine malposition of the fetus leads to malformations; it seems just as reasonable, however, to consider malposition secondary to the malformation. There is a possibility that a deformed fetal part which assumes an abnormal position impairs the normal development of another part and thus causes secondary deformities (mutilations). Amniotic bands are sometimes associated with malformations, but there is no proof that they are the cause of the deformities. More probably they are the result of the genetic or environmental disturbance that caused the malformations.

**Chemical Injuries.** Certain chemicals are capable of destroying the embryo, and, in lower animals, malformations can be produced by adding toxic substances to the environment. The evidence for similar effects on mammalian embryos is scant. Alcohol, benzene, nicotine, lead, mercury and iodine have been suspected as injurious agents, but experimental results have been contradictory. Quinine taken by the mother during pregnancy may cause congenital deafness in her child.

**Nutritional Disturbances.** Nutritional disturbances may adversely influence the embryo. Faulty implantation of the ovum and degeneration of the chorion may interrupt the nutrition of the embryo and disturb its development. Malformation in fetuses derived from ectopic pregnancies is mentioned above. Deficiencies of other nutritional constituents of the maternal diet and deficiency of oxygen have been responsible for defective offspring in animal experiments, but there is no proof that these observations can be applied to human beings. In many regions of Europe, Asia and South America endemic goiter of the parents is associated with endemic cretinism.

the children. The serious mental and physical retardation of the offspring is usually attributed to a lack of iodine in the maternal diet. However, a positive goitrogenic factor may also contribute to this anomaly.

Extensive studies have shown a significant relation between the diet of pregnant women and the physical condition of newborn infants. Stillborn, premature and functionally immature children are born more often to mothers whose diet is poor during pregnancy than to mothers whose diet is adequate. General starvation, as in war or famine, leads to a sharp fall in the conception rate which is associated with amenorrhea. Infants born after periods of dietary deprivation show a reduction in birth weight and birth length.

**Injuries from Infection.** Severe maternal infections during early pregnancy often result in abortion. Mothers who have had German measles during the first two or three months of pregnancy may give birth to infants with congenital cataracts and other congenital defects. Prenatal toxoplasmosis may also result in congenital hydrocephalus, microcephaly and chorioretinitis, as well as widespread disease.

Infections of the fetus during the latter stages of prenatal life cause manifestations which more closely resemble those of postnatal life. Smallpox has been observed in fetuses older than three months; the fetus may recover and be born with scars. Rare

cases of fetal measles and scarlet fever have been reported. Placental transmission of typhoid and tubercle bacilli occurs occasionally, and that of *Treponema pallidum* is common in infected, untreated mothers.

**Actinic Injuries.** Roentgen rays and radium rays are capable of arresting embryonic development and producing malformations. Microcephaly, mental retardation, spina bifida, deformities of the extremities, and the like, have been ascribed to such intrauterine injuries.

**Other Factors.** In addition to the pathogenic environmental factors considered, there may be others still unrecognized. The possibility that abnormal endocrine factors influence the development of the embryo deserves consideration. Diabetic mothers treated with insulin often have abortions and stillbirths, and the neonatal death rate of their infants is high. Cortisone injected into pregnant mice or rabbits may induce cleft palate and other malformations in the fetus.

The etiology of mongolism appears to be related in some way to the age of the mother at the time of the birth of the mongolian idiot. The average age of mothers at such times is significantly higher than the average age of mothers at the birth of normal children.

Advanced maternal age may also play a role in the etiology of other congenital defects such as chondrodystrophy.

## CONGENITAL MALFORMATIONS

More deaths occur in the first month of life than in the remaining months of the first year, and the decline in the infant mortality rate in recent years is less in the neonatal period. This is not surprising if the neonatal mortality is regarded in part as a continuation of the process of "natural selection" which eliminates defective embryos and fetuses throughout the intrauterine period.

Structural anomalies of the embryo play a leading role in the mortality of the first trimester of intrauterine life. Most abnormal embryos die early, but structural anomalies may be compatible with intrauterine life. Shortly before and after birth (perinatal period) the fetus must adjust itself to the profound physiologic changes associated with the onset of extrauterine life. Many abnormal fetuses are incapable of doing so and die at

this time. They contribute considerably to the peak of mortality, which occurs in the perinatal period. About 20 per cent of the deaths occurring in the third trimester of gestation and about 15 per cent of those in the neonatal period are attributed to gross congenital malformations. Although the elimination of deformed children decreases markedly after the first month of postnatal life, the process of natural selection continues throughout infancy and childhood.

According to the vital statistics of the United States, 20,012 deaths were attributed in 1953 to congenital malformations. In the same year whooping cough, measles, diphtheria, scarlet fever and poliomyelitis combined caused 2544 deaths. A comparison of these data illustrates the relative importance of malformations as a cause of death.

Many children with congenital malformations are permanently disabled. Malformations such as clubfoot, dislocation of the hip, spina bifida, and the like, are among the leading causes of crippling in childhood.

The role of congenital malformations in the causation of diseases of children is difficult to evaluate. Some defects, such as those of the osseous system, the heart and the intestinal tract, are well recognized, but many malformations are encountered in disguise. Many congenital defects may go unnoticed for years, particularly those within the body. The affected organs may function for some time, but fail when faced with increased demands. Congenital malformations are often predisposing factors to disease because they represent points of inadequate resistance; they can be damaged by minor infections, toxins or traumas which are usually tolerated by the normal organism without serious consequences. Diseases resulting from such a combination of circumstances may be attributed to the eliciting factor, while the underlying malformation is overlooked.

The primary cause of so-called renal rickets may be a congenital obstruction of the urinary tract. Dwarfism, malnutrition, osseous changes, polyuria, polydipsia, renal insufficiency, chemical changes of the blood, infections of the urinary tract or other symptoms may dominate the clinical picture. Obviously treatment of the symptoms enumerated will not meet with success, whereas early detection and removal of the congenital obstruction may lead to permanent cure.

Many cases diagnosed as chronic pyelitis, chronic pneumonia, malnutrition, birth injury, and the like, represent symptoms of diseased congenital defects; certain nervous disorders and endocrine disturbances are caused by prenatal developmental errors. Many tumors of infancy and childhood can be attributed to congenital malformations (see p. 1347). Congenital defects of the brain play an important role in mental deficiency.

Congenital malformations need not be grossly demonstrable, but may be defects of histologic structure. The role of misplaced cells in the genesis of certain tumors is well known. Some disorders of the nervous system or the endocrine glands must be attributed to histologic congenital defects. Spherocytosis is a congenital anomaly. The intimate relation of certain forms of anemia to malformations is indicated by their association in syndromes. For example, in some forms of aplastic anemia, association with congenital

defects of the skeleton, heart and genital tract points to the developmental origin of the disorder (e.g., Fanconi's anemia).

#### ETIOLOGY AND PATHOGENESIS

Little is known about the causes of congenital malformations in man. Maternal rubella in the first trimester of pregnancy, toxoplasmosis and exposure of the mother to roentgen rays are probably the only known events for which a causative relationship is recognized. A great deal is known, however, about mechanisms and circumstances which favor developmental errors. Such knowledge is derived from clinical observation of patients, from investigation of their families and their environment, and from animal experiments.

Many congenital anomalies are genetically determined. Such anomalies are caused by mutations of genes or chromosomal aberrations which occurred in an immediate or remote ancestor of the affected person. In plants and animals, mutations can be induced experimentally by radiation, but nothing is known about the causes of mutations in man. Some congenital defects are inherited like mendelian unit characters. The laws of inheritance explain the mechanism of the transmission and make possible statistical predictions concerning their reappearance in the offspring of affected persons and their relatives.

Animals often inherit congenital malformations with great regularity of pattern, and it is possible to make a systematic examination of their embryos of different ages to ascertain step by step the deviations from normal development. In this way the action and mechanism of the abnormal gene can be investigated at the development of the finished character observed.

The embryo requires adequate nutrition for normal growth and differentiation. Interruption of nutrition results in death of the embryo, and it is suggested that minor disturbances of the metabolic exchanges between mother and embryo may lead to malformations of the developing organism. The chorion of pathologic embryos is frequently diseased but it is difficult to decide whether the chorionic changes are responsible for the abnormal development or whether an inherent anomaly of the fetus incompatible with life leads to secondary changes of the chorion. Abnormal fetuses are sometimes found in uterus which appears histologically normal. On the other hand, there is a high incidence of congenital defects in fetuses derived from ectopic pregnancies, which have been attributed to faulty implantation.

Experimental observations indicate that chemical changes of the environment can alter the development of the embryo. At certain stages of development minor abnormalities can produce severe anomalies. Maternal diseases and hormonal disturbances could change the chemical environment of the human embryo. Suggestive of such a causal relationship is the relatively high incidence of congenital malformations in children of diabetic mothers and of mothers in their late childbearing period. The mechanism of abnormal development in such cases is not understood, but possibly an undetected anomaly of the chemical environment of the embryo may be responsible.

As previously noted, severe infections of the mother in early pregnancy often result in abortion, and relatively mild infections with the rubella virus in the first trimester of gestation may result in a variety of congenital anomalies of the fetus. There is no proof that these viruses have a comparable teratogenic effect.

*Although the origin of most congenital defects in man is obscure, some general conclusions can be drawn. Congenital malformations are the result of prenatal pathologic processes which can be determined by the genetic constitution of the embryo and take their course in spite of favorable environmental conditions, or a genetically normal embryo can be deformed by adverse environmental circumstances. It follows that not all congenital malformations are hereditary. It is likely, however, that most congenital malformations are the result of interaction between genetic and nongenetic (environmental) factors.*

Teratogenic factors are not specific, and the lack of specificity manifests itself in two ways. An injurious agent may cause various types of abnormalities, according to the time or intensity of its action, as illustrated by the wide variety of congenital anomalies induced by maternal rubella. Maternal roentgen-ray irradiation results in abnormalities in the offspring, which vary with the dose applied and the gestational period in which the exposure took place. An abnormal gene may manifest itself in various abnormalities and exercise a pleiotropic effect. Conversely, a specific type of malformation may be caused by different etiologic factors. For example, each of the three pathologic conditions illustrated in Figures 54, 55 and 56 can be attributed to three different causes. Hereditary and nonhereditary forms may resemble each other; it should not be concluded, therefore, that all forms of

cleft palate or syndactylysm are hereditary because heredity has been proved in some instances.

In spite of the variability of syndromes, it is of definite value to study and record combinations of defects frequently encountered. A knowledge of such syndromes may be an aid in diagnosis and prognosis, particularly if one keeps in mind that the association of defects may vary. This will be illustrated by two examples. Night blindness may be due to a deficiency of vitamin A, but it is also a symptom of retinitis pigmentosa, a degenerative process of the retina which is a constituent of the Laurence-Moon-Biedl syndrome. Night blindness in a child with polydactylysm, obesity and mental retardation assumes, therefore, a different aspect from that in an otherwise normal child. The diagnosis of mental retardation is difficult in the neonatal period. The presence of hypertelorism, epicanthal folds, slanting eyes and other somatic anomalies makes possible, however, the diagnosis of mongolism, with all its prognostic implications, immediately after birth.

Besides such well established syndromes, many combinations of congenital defects are encountered which have not been described or named. Thus, in children with congenital heart disease, conditions such as cleft palate, polydactylysm, malformations of the kidney, atresia ani, encephalocele, hydrocephalus and mongolism are more frequent than in the average children's population. The occurrence of external and skeletal defects in children with mental deficiency is well known. Such visible defects have been considered "stigmata of degeneration." Though this term is ill chosen, it is correct that malformations are found more often in patients with mental deficiency of prenatal origin than in mentally normal children. It is useful to keep this principle of multiplicity of malformations in mind when there is doubt whether one is dealing with a congenital or an acquired disorder in a patient. The finding of one or several additional malformations makes prenatal origin of the disorder more likely.

Malformations may occur sporadically or repeatedly in a sibship (p. 234). Identical malformations, such as cleft palate, may be found in several members of a pedigree. In other instances, one member may have microphthalmus and another glioma retinae. Entire syndromes may recur in families. Thus gargoylism or the Laurence-Moon-Biedl syndrome has been observed repeatedly in a single family. But the various symptoms of a

(Engelking: *Klin. Monatschr. f. Augenh.*, Vol. 94.)

(All figures from Warkany, in *Advances in Pediatrics*. Interscience Publishers, Inc., Vol. 2.)

syndrome may also be dissociated in a family, one member showing one symptom or one group of symptoms, and other members showing another part of the syndrome. Thus one child may have the entire Laurence-Moon-

Biedl syndrome, while another child of the same family is mentally retarded and obese, and a third child has mental retardation and polydactylism. In spite of such irregularity the family history is often a great aid in

gnosis and prognosis of the disease of an individual.

It is useful to regard congenital malformations as one form of reproductive failure. Whenever environmental or genetic factors are unfavorable for reproduction, various manifestations of reproductive failure are observed. The most unfavorable conditions are sterility. Between this extreme and the most favorable one which leads to normal reproduction, abnormal borderline states exist. Stillbirth, premature birth and perinatal death may be expressions of such borderline conditions. Malformations contribute to all degrees of reproductive failure and are a substantial cause of abortions in the first trimester. Deformed fetuses which reach the end of the normal gestational period and are born in the perinatal period or survive birth represent a relative reproductive "success" when compared with sterility or early abortion. This possibility makes it understandable that an improvement of reproductive conditions may result in a higher incidence of

congenital malformations. It explains why the true incidence of malformations cannot be estimated without a thorough examination of the aborted and stillborn fetuses.

In experiments one can produce congenital malformations in animals by planned creation of adverse borderline conditions or by applying injurious agents which damage the embryo without killing it. However, starvation, severe infection of the mother or traumatic injury of the embryo may not result in malformations, because they are lethal for the embryo. Even genetically determined malformations may not become "congenital"; i.e., the embryo may not live to the period of birth if two abnormal genes direct the development. Between the lethal homozygous state and normality there may be a borderline condition, the heterozygous state. The heterozygous person is viable and affected with a congenital malformation. These examples illustrate how closely related are the causes of congenital malformations to other forms of reproductive failure.

## ADVISABILITY OF PARENTHOOD

Interest in prenatal pathogenic factors originated with the desire to prevent their disastrous results. In many instances eugenic measures or advice may contribute to the well-being of children as yet unborn.

If a person or one of his close relatives suffers from a congenital defect, he may ask his physician whether he should have children; or parents who have had a defective child may ask whether they should have more offspring. Such questions can rarely be answered adequately, but a knowledge of the facts discussed in the foregoing pages may serve as a guide.

In general it is preferable to give the parents all the available facts concerning the etiology, the theoretic chance of transmission of the disorder, and its clinical course rather than to advise them whether or not to have children. Many factors not medical enter into such a decision, such as the parents' desire of having children, the size of the family, the age of the parents, economic circumstances and religious convictions.

It is important to ascertain whether a given defect or disorder is hereditary or not, since the prognosis for procreation will differ greatly in cases of genetic origin from those of

postconceptional damage. In certain instances such a differentiation can be made without difficulty; in many it may not be possible. Before a statement is made concerning the heredity of a trait the following considerations should be taken into account.

Not all congenital anomalies and defects are hereditary, and not all hereditary anomalies are congenital. The defects produced in the fetus by maternal rubella or toxoplasmosis are congenital, but not genetically determined and, therefore, not hereditary. On the other hand, hereditary traits such as Friedreich's ataxia, Huntington's chorea, diabetes mellitus, retinitis pigmentosa and many others are not congenital, but develop at various periods of postnatal life. The terms "congenital" and "hereditary" are not synonymous.

The widespread belief that anomalies which occur repeatedly in a family are hereditary, whereas those which appear sporadically are not, is not necessarily correct. A defect may be genetically determined, although only one known member of the sibship shows the trait. The defective person may be the first to manifest the genic mutation. In the case of a dominant hereditary trait, his ancestors and siblings are free of the trait, but half of his

children have a chance to have the anomaly and to pass it on to half of their children. This illustrates that sporadic occurrence of a congenital anomaly does not assure normal offspring to the (first) affected member. Similarly, genetically determined defects may appear sporadically if they depend upon recessive factors or if by chance a limited pedigree does not include other defective members. The repeated occurrence of a defect in a pedigree does not prove, however, that it is genetically determined, since several members of a sibship may be exposed to the same pathogenic environmental factors. Thus endemic goiter, rickets, pellagra, and the like, are often familial, but they are usually not hereditary and may be prevented by a change of dietary habits. "Familial" and "hereditary" are not synonymous terms.

Differentiation between hereditary and nonhereditary anomalies is further complicated by the fact that the clinical picture of a nonhereditary modification may resemble closely that of a hereditary mutation. Thus congenital cataract is hereditary in some families, but cataract in an infant whose mother had German measles during the first two months of pregnancy is of environmental origin. Epileptiform convulsions can be inherited or may be due to natal or postnatal trauma. Similarly, syndactyly, cleft palate, microcephaly, spina bifida, microphthalmus and many other congenital defects may be due to genetic mutation, to environmental modification, or to a combination of the two.

The history of pregnancy should include a description of the mother's state of health during the early weeks of pregnancy and of any roentgen ray or drug therapy. Organogenesis is finished at approximately twelve weeks of gestation, and most severe malformations such as congenital heart disease, spina bifida, colobomas of the eye and cleft palate are determined by that time. The rest of gestation is devoted essentially to growth of the fetus. Interference during the latter phase of development may result in a different type of congenital anomaly, such as hydrocephalus, microphthalmus, chorioretinitis and malposition of the extremities. Threatened abortions, diseases and traumas of the mother should be recorded.

The birth history may indicate that physical and mental anomalies can be attributed to injuries received during delivery.

Taking the family history is a time-consuming but necessary procedure. The mother's and the father's ages should be recorded, and

the parents should be asked whether they are blood-related (consanguineous). It is usual to make a pedigree chart (p. 237), but this is usually impractical in a busy clinic. Initially, the medical history of the patient (propositus) is recorded, then that of his brothers and sisters. Miscarriages, stillbirths and causes of deaths of siblings are also recorded. Healthy persons as well as the defective ones must be included in the family history. Next the medical histories of the grandparents, their siblings and siblings' offspring, and so on, are obtained until the pedigree is traced backwards and collaterally as far as the information is reasonably reliable.

If a pathologic trait known to be usually dominant appears in a family and if the pedigree of that family suggests dominant inheritance, it is possible to give a eugenic prognosis. An affected parent who marries a mate normal for the character in question can be told that his children have only a 50% chance to be normal. However, if the parent comes from a family affected by a dominant pathologic trait without showing it, he cannot be assured that he will not transmit the trait to his offspring. Before such assurance is given it should be established that the inheritance of the trait has complete penetrance and expressivity (p. 236), since otherwise a person may appear normal, but transmit the trait. In cases of variable expressivity a person may appear normal on superficial examination, but reveal an abnormal trait in a mild form when subjected to special examinations.

Multiple exostoses are usually well developed in affected males, but in affected females may be so small that the carriers may not be conscious of them. If roentgenograms of the prospective mother reveal slight osseous excrescences in places where exostoses usually occur, she is likely to transmit the disorder, and her sons could be severely affected.

At times laboratory tests can aid in detecting carriers of an abnormal trait with variable expressivity. A member of a family affected with hemolytic jaundice may be clinically well, but have spherocytosis and increased fragility of the red cells which is revealed only by special tests. "Carriers" of gout can be discovered by chemical examination of the blood, since they have hyperuricemia. In addition, before a member of an affected family is declared free, one must be sure that he has reached an age after which the onset of the disease is unlikely. Since cerebellar ataxia may not begin before the fourth decade, no member of an affected family should

considered normal before reaching the age forty years. These examples demonstrate that even in dominant inheritance a eugenic prognosis must be made with caution.

Analysis and prognosis of a recessive trait is more difficult. Such a gene can be carried in the heterozygous form through many generations without causing visible effects, and the abnormal trait can appear in about one-fourth of the children of normal parents who are both heterozygous carriers. Such cases are sometimes so sporadic that their distinction from nonhereditary similar conditions (anecdotical cases) may be impossible. On the other hand, if a homozygous person who has the trait marries a heterozygous carrier who appears normal, the children have a 1:1 chance to be homozygous and to exhibit the trait. Such a pedigree simulates that of a family in which a dominant trait is transmitted through two generations. When two persons homozygous for a recessive trait marry, all the children must be expected to be abnormal.

Deaf-mutism is sometimes genetically determined, the gene being recessive. A deaf-mute is homozygous for the trait. If two persons of this type marry, one can predict that their children will be deaf-mutes (see Fig. 48). If, however, a person with such hereditary deafness marries a normal mate or a person with acquired deafness, all the children can be expected to have normal hearing, although they will be carriers of the abnormal trait (Figs. 48, 49). If two carriers who have an abnormal (homozygous) child ask about the chances of a second child, they must be told that the following child has again one chance in four to be affected. The chances that two heterozygous carriers meet are enhanced by consanguineous marriages in families in which recessive pathogenic genes occur.

A man who manifests a sex-linked recessive trait will—with a normal wife—have sons who neither show nor transmit the trait; but all his daughters will be carriers. The sons of such female carriers will have a 1:1 chance of showing the abnormal trait; those sons who do not manifest the disorder do not transmit it. All the daughters will appear normal, but have a 1:1 chance of being carriers like their mother. There is usually no way to distinguish the carrier daughters from their normal sisters unless their offspring reveal their heterozygous state.

Hereditary traits may be transmitted differently in different sibships. It was mentioned

before that polydactylism, chondrodystrophy, glioma retinae and many other anomalies are sometimes inherited in a dominant and sometimes in a recessive manner. Progressive muscular dystrophy, peroneal atrophy and microphthalmus are transmitted in some families as dominant, in some as recessive, and in others as sex-linked recessive traits.

If a congenital anomaly was caused by an environmental accident, the prognosis for a subsequent pregnancy will depend upon the kind of interfering agent. If the child's anomalies are due to maternal rubella or toxoplasmosis, the prognosis for a second child is good. If they are due to administration of therapeutic doses of roentgen rays or toxic drugs and a repetition of the faulty treatment can be avoided, the prognosis is good.

The etiology of mongolism is unknown, but the theory has been advanced that abnormal heredity and environment may act in combination. In this case the environment is thought to be rendered abnormal by factors resulting from the advanced age of the mother. Two or more cases of mongolism have occurred in one family, but this is exceedingly rare. Young mothers who have given birth to a mongoloid child have a good chance to have normal children subsequently.

When neither a definite genetic nor a known environmental factor can be made responsible for a congenital defect, the chances for the outcome of a subsequent pregnancy cannot be estimated.

When possible, it is helpful to indicate to parents the approximate chances for normal or abnormal children. Such empirical risk figures have been worked out for some congenital disorders such as epilepsy, diabetes mellitus, cardiac malformations, facial clefts, clubfoot and others. Since such disorders are of heterogeneous origin, empirical risk figures represent merely average risks for the disorder in question, which should be used only when actual risk figures cannot be had.

If, for instance, normal parents have a child with harelip (with or without cleft palate), the average risk for another child having a similar malformation is about 5 per cent. If the parents have had two affected children, the risk of having still another is about 10 per cent. If one parent has the anomaly, the average risk for a child is 2 per cent. If, however, in a family one parent and one child are affected, the risk for other children being affected is about 12 per cent. The risk figures are somewhat different for cleft palate without harelip. If the parents are

unaffected, but one child has cleft palate, the risk of having this malformation is about 3 per cent for subsequent children. If one parent has the anomaly, the risk for a child is said to be 7 per cent, but this estimate is questionable, since it is derived from a small sample. If one parent and one child are affected, the risk for other children is said to be 17 per cent.

Such risk figures are better than none at all, but they should be considered merely provisional estimates.

**Protection of the Mother.** Eugenic measures and advice are not restricted to the genetic aspects of prenatal life. The normal development of the fetus should be assured as far as possible by protection of the expectant mother from adverse environmental influences. Roentgen ray treatment must be avoided whenever there is the possibility of a pregnancy. It is of great importance to point out that the first three months of pregnancy are decisive in the formation of the organs of the child, and that the embryo in its early stages is more vulnerable than the fetus.

## INBORN ERRORS OF METABOLISM

Sir A. E. Garrod's classic paper (1902) on the abnormal human biochemical trait, alcaptonuria, presented the first evidence that each gene was concerned with a specific biochemical process in cellular metabolism. Extensive studies by biochemical geneticists in plants, bacteria and animals greatly stimulated the clinical interest in the human hereditary biochemical disorders, which Gar-

rod had named *inborn errors of metabolism*. Investigation of inherited flower color differences, for example, defined the specific role of numerous single genes in modifying chemically the organic nucleus, 2-phenylbenzopyrylium, to form the different anthocyanin and anthoxanthin compounds which are the blue, red and yellow pigments of flowers. Many of the demonstrated complexities

etic control of the pathways for biosynthesis of vitamins, amino acids and the like, the protoplasm of the fungus, *Neurospora*, and their prototypes in the human cell. Studies of the synthesis of nucleic acids in mutant strains of *Escherichia coli* and phages are furnishing knowledge of the chemical nature of the gene and of basic biochemical mechanisms under genetic control, which is applicable to all cellular metabolism. The detection of two inherited enzymatic activities in the rabbit, xanthophyllase, which defines the deposition of yellow fat, and ascorbic acidase, which inactivates atropine, is a forerunner of the expanding body of human observations which forms the basis for the concept of human biochemical individuality—that the uniqueness of each human being derives from the genetically determined chemical patterns in his cells.

Important additions to the knowledge of normal human dynamic biochemistry are being made by the recent rapid growth of clinical and investigative interest in the inborn errors of metabolism. The current concept is that each gene is normally responsible for the production of a specific biologically functional macromolecule which is often, but not necessarily, an enzyme. To emphasize the association of a specific molecular abnormality with a mutant gene, Pauling renamed the disorders, "the molecular diseases." Several different mechanisms are postulated to explain the ways in which the molecular diseases produce clinically detectable biochemical abnormalities:

1. By producing a metabolic block at one stage in a series of chemical transformations, resulting in either (a) an accumulation of a normally occurring metabolite, present in undetectable amounts, e.g., the accumulation and excretion of phenylpyruvic acid in phenylketonuria; or (b) a failure of production of an essential normal end product, e.g., the absence of melanin pigments in albinism.

2. By the abnormality or absence of an enzymatically regulated renal tubular transport mechanism, leading to (a) excessive urinary loss of an essential metabolite because of tubular reabsorptive failure, e.g., cystine in cystinuria; or (b) accumulation of a catabolic end product in the body fluids because of excessive tubular reabsorption, e.g., uric acid in gout.

3. By replacement of a normally occurring enzyme or enzymatic process by another with different activity, resulting in the synthesis

of compounds unlike those usually found in man, e.g., the abnormal hemoglobins.

Patients with the same molecular disease may show individual differences in clinical findings, ranging from complete absence of signs and symptoms to severe illness of varying duration. Such variability may be due to a peculiarity of the genetic defect itself, which is termed the *degree of penetrance* of the mutant gene. In persons carrying the same mutant gene, *genotypes*, variations in degree of penetrance of the gene account for differences in clinical appearances or manifestations, *phenotypes*. More amenable to medical intervention, however, are the influences of environmental factors in determining the clinical manifestations or phenotypes of a given molecular disease. This is referred to as the *degree of expressivity* of the genetic defect. The prevention of the symptoms of galactosemia by a galactose-free diet exemplifies this latter concept.

A meaningful classification of the ever-growing number of molecular diseases would be one based upon the framework of normal human dynamic biochemistry. The fragmentary knowledge of this vast area, and the ignorance of the specific genetically determined biochemical defect in most molecular diseases, make this impossible at present. A temporarily convenient grouping, which lists the inborn errors of metabolism under the chemical species by which they are detectable clinically, is the following:

Table 46. Inborn Errors of Metabolism ("Molecular Diseases")

#### I. Errors in Protein Metabolism

##### A. Defective synthesis of plasma proteins (dysproteinemias)

1. Familial idiopathic dysproteinemia
2. Idiopathic hypoproteinemia
3. Congenital afibrinogenemia
4. Hemophilia (A) and mild hemophilia (AHG)
5. Hemophilia B (plasma thromboplastin component, PTC, deficiency or Christmas disease)
6. Plasma thromboplastin antecedent (PTA) deficiency (hemophilia C)
7. Hageman factor (HF) deficiency
8. Labile factor deficiency (parahemophilia or Owren's disease)
9. Stable factor deficiency (serum prothrombin conversion accelerator, SPCA, deficiency)
10. Stuart factor deficiency
11. Congenital hypoprothrombinemia
12. Agammaglobulinemia

Table 46 (continued)

13. Congenital absence of specific beta-2-globulin with immunologic paralysis
14. Absence of  $\beta$ -2-globulins (haptoglobins) causing hemoglobinuria
15. Ceruloplasmin deficiency in Wilson's disease
16. Congenital analbuminemia
- B. Defective hemoglobin synthesis
  1. Abnormal hemoglobin (S, C, D, E, G, H, I, J, K, L, M, N, O, P, Q, Bart's hemoglobin), diseases and traits
  2. Thalassemia major and minor
  3. Sickle cell variants (combinations of 1 and 2)
- C. Defective amino acid metabolism and transport of amino acids
  1. Of phenylalanine and tyrosine
    - a. Alcaptonuria
    - b. Phenylketonuria
    - c. Tyrosinosis
    - d. Albinism
    - e. Sporadic goitrous cretinism (p. 1170)
  2. Of cystine (and glutathione)
    - a. Cystinuria, the prototype of inherited syndromes of renal tubular dysfunction. Includes glycinuria, beta-aminoisobutyric aciduria, renal glycosuria, vitamin D-resistant rickets, nephrogenic diabetes insipidus, pseudohypoparathyroidism, variants of the Fanconi syndrome and others
    - b. Cystinosis
    - c. Hereditary tendency to drug-induced (primaquine, etc.) hemolytic anemia (involving glutathione)
  3. Of tryptophane
    - a. Congenital hypoplastic anemia (erythrocytogenesis imperfecta)
    - b. Hartnup (H) disease
    - c. Autism with hereditary error in tryptophane metabolism
  4. Of lysine
    - a. Hypoglycemia (idiopathic)
  5. Of valine, leucine and isoleucine
    - a. Maple sugar disease
- II. *Errors in Carbohydrate Metabolism*
  - A. Defective mucopolysaccharide metabolism
    1. Hurler's disease (gargoylism) (p. 1238), Marfan's syndrome (p. 1243) and osteogenesis imperfecta (p. 1241)
  - B. Defective glycogen metabolism
    1. Glycogen storage disease of liver and kidneys (von Gierke)
    2. Glycogen storage disease with hepatic cirrhosis (brancher enzyme defect)
    3. Glycogen storage disease of liver and muscle (debrancher enzyme defects)
    4. Glycogen storage disease of heart and muscles

Table 46 (continued)

5. Glycogen storage disease of skeletal muscle
- C. Defective disaccharide metabolism
  1. Congenital sucrosuria
- D. Defective hexose metabolism
  1. Essential fructosuria
  2. Galactosemia (congenital galactosuria)
- E. Defective pentose metabolism
  1. Essential pentosuria (xylulosuria)
- III. *Errors in Lipid Metabolism*
  - A. Defective neutral fat metabolism
    1. Idiopathic hyperlipemia
  - B. Defective cholesterol metabolism (p. 1002)
    1. Primary xanthomatosis of the hypercholesterolemic type (hereditary hypercholesterolemic xanthomatosis) manifested as the following clinical syndromes:
      - a. Xanthoma tuberosum et planum (skin)
      - b. Xanthoma of the tendons
      - c. Xanthoma of the intima of blood vessels and heart
      - d. Forme fruste, i.e., hypercholesterolemia alone
      - e. Xanthomatous biliary cirrhosis
    2. Congenital adrenal hyperplasia, syndromes of (virilizing adrenal hyperplasia)
      - a. Early virilization in either sex, pseudohermaphroditism in females
      - b. Early virilization, precocious growth and hypertension
      - c. Early virilization, precocious growth and disturbed electrolyte metabolism (salt losers)
  - C. Defective diaminophosphatide (sphingomyelin) metabolism
    1. Niemann-Pick disease (sphingomyelin lipoidosis) (p. 1000)
  - D. Defective cerebroside metabolism
    1. Gaucher's disease (cerebroside lipoidosis) (p. 999)
  - E. Defective ganglioside metabolism
    1. Tay-Sachs disease (amaurotic familial idiocy) (p. 1094)
- IV. *Errors in Pigment Metabolism*
  - A. Defective porphyrin metabolism, the porphyrias
    1. Congenital (erythropoietic) porphyria
    2. Acute intermittent porphyria
    3. Cutanea tarda type of porphyria
  - B. Defective bilirubin excretion
    1. Hereditary obstructive jaundice
  - C. Defective hemoglobin pigment
    1. Hereditary methemoglobinemias
    2. Hereditary sulfhemoglobinemia
  - D. Hemochromatosis
- V. *Unclassified*
  - A. Hypophosphatasia (p. 1224)
  - B. Congenital spherocytic anemia (p. 944)
  - C. Oxalosis (p. 1054)

## INBORN ERRORS IN PROTEIN METABOLISM

Genetic abnormality of the various body proteins, estimated to number 100,000, could produce a staggering variety of structural and functional human hereditary disorders. Basic chemical defects are being uncovered in human genetic diseases, once known only by their morphologic and functional features. Exemplifying this are arachnodactyly, in which a widespread connective tissue defect

is apparently based upon disordered structure of fibrous proteins or upon abnormal basic molecules of collagen and elastin; and muscular dystrophy, in which abnormality of the contractile proteins of muscle cells is a basic defect. Because the disordered chemistry of these two true molecular diseases is still somewhat ill-defined, they and many others are omitted from this section.

### *Defective Synthesis of Plasma Proteins*

The number of genetic errors in the synthesis of plasma proteins continues to increase. For example, the isolation of gamma globulin and the demonstration that it is a carrier of immune antibodies made possible the discovery that a group of children who failed to acquire immunity to various infectious agents suffered from a congenital defect in the synthesis of gamma globulin. And the congenital absence of certain single fractions of the globulins which enter into the complex mechanism of blood clotting has been shown to be responsible not only for hemophilia, but also for an array of disorders with abnormal bleeding tendencies. The term "dysproteinemia" has been applied to hereditary disorders of plasma proteins.

#### **FAMILIAL IDIOPATHIC DYSPROTEINEMIA**

Familial idiopathic dysproteinemia is a hereditary disorder characterized by hypoproteinemia with or without abnormalities in the electrophoretic patterns in the plasma. In the family in which the disorder was first detected four adults of one generation, two of their paternal uncles and four members of the second generation had hypoproteinemia with a variety of changes in concentration of various serum protein fractions. Edema occurred in adult members of the family, with ulcers of the legs in male members and low oscillometric readings in females.

#### **IDIOPATHIC HYPOPROTEINEMIA**

Congenital and persistent hypoproteinemia is a rare disorder. The two cases recorded in this country had fluctuating edema associated with low globulin and albumin values. One patient, a twelve-year-old child, had not had

recurrent infections, even though serum gamma globulin was absent by electrophoretic analysis. The second, a child three years of age, showed atrophic liver changes at autopsy. Whether these were the cause or the result of the hypoproteinemia is not known. In both instances, however, it appears that a defect in the synthesis of serum protein was responsible for the hypoproteinemia. Congenital hypoproteinemia is unrelated to the recently delineated syndrome of hypoproteinemia and anemia of a transitory nature in young infants, which has been named transient dysproteinemia.

#### **CONGENITAL DEFECTS IN THE SYNTHESIS OF PLASMA PROTEINS ACCOMPANIED BY HEMORRHAGIC DIATHESIS**

The relationship of the hemorrhagic disorders dependent upon a deficiency or absence of one or another of the plasma proteins concerned in the clotting mechanism is shown in Figure 57.

A clot forms when soluble fibrinogen is converted to insoluble fibrin through the enzymatic activity of thrombin. For its activation to thrombin, prothrombin requires the following five substances: (1) thromboplastin, which is derived from platelets (platelet factor 3) or tissue extracts and becomes active through modification by four separate components of plasma protein, antihemophilic globulin (AHG), plasma thromboplastin component (PTC), plasma thromboplastin antecedent (PTA) and Hageman factor (HF); (2) calcium (ionic); (3) labile factor in an active form derived from an inactive form by the action of small amounts of thrombin; (4) stable factor; and (5)

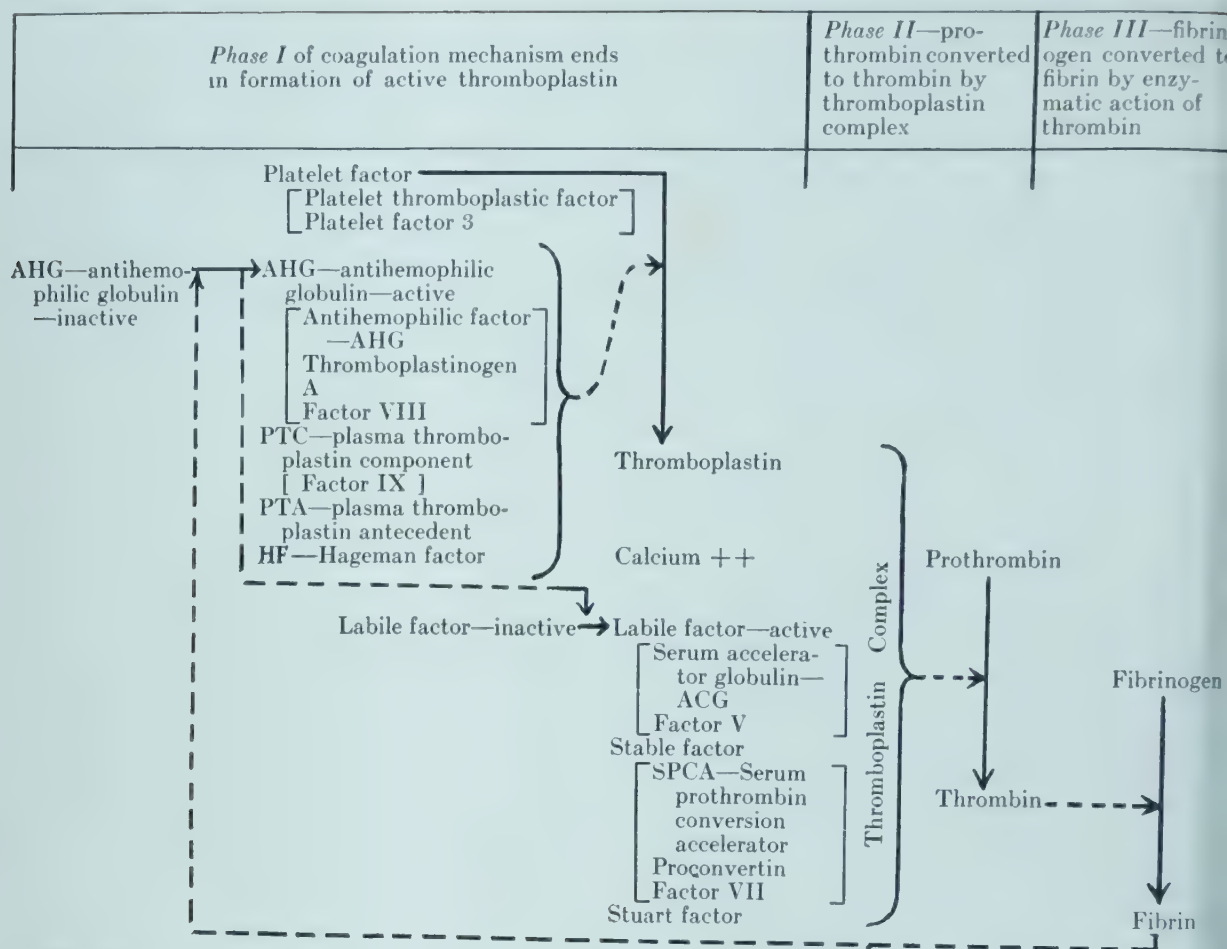

FIG. 57. Schema of postulated blood coagulation process. Solid arrows indicate conversion of one substance to another. Broken arrows indicate activation of the process; other commonly used names for individual constituents are listed under each one between brackets. At the top of the figure is depicted the division of the coagulation mechanism into its three phases ending in thromboplastin, thrombin and fibrinogen formation, respectively. Clinical entities are associated with inherited defects in formation of fibrinogen (afibrinogenemia), antihemophilic globulin-AHG (classic hemophilia A), plasma thromboplastin component-PTC (Christmas disease or hemophilia B), plasma thromboplastin antecedent-PTA (hemophilia C or PTC deficiency), Hageman factor-HF (Hageman trait), labile factor (parahemophilia or Owren's disease), stable factor (serum prothrombin conversion accelerator, SPCA deficiency), Stuart factor deficiency, prothrombin (congenital hypoprothrombinemias, types I and II).

Stuart factor. The formation of a clot ceases when the small amount of thrombin which initiated the process is absorbed upon the fibrin clot so formed.

*Afibrinogenemia* (p. 482) or hereditary absence of fibrinogen from the blood is due to a rare recessive gene. Thirty-one cases, affecting both sexes, are recorded. Though death in early infancy and early childhood is common, one patient was in excellent health at the age of twenty-one years.

*Hemophilia* (p. 977) (classic hemophilia or hemophilia A) is due to a failure or deficiency in synthesis of the antihemophilic globulin (AHG). In *mild hemophilia*, an allelic form of hemophilia, AHG is present in variable amounts up to 25 per cent of normal, so that bleeding is less severe than in hemo-

philia. Both degrees of hemophilia are sex-linked recessive traits, carried by females and appearing in males. The mild form is not completely recessive, however, since certain female carriers tend to bruise easily and to have menorrhagia. In several families hemophilia has occurred in females. A variety of hemophilia in which, in addition to the customary findings of reduced AHG concentration and prolonged coagulation time there is an increased bleeding time and capillary fragility, has been termed *vascular hemophilia* or *pseudohemophilia* (p. 980). It is apparently transmitted by an autosomal dominant gene of high penetrance and variable expressivity.

*Hemophilia B* (p. 980) (plasma thromboplastin component, PTC, deficiency; Christ

nas disease or deuterohemophilia) is inherited as a sex-linked recessive trait, causing an absence or deficiency of PTC. Less severe than hemophilia in males, there is a greater incidence of bleeding manifestations in heterozygotes for the PTC factor. From 10 to 20 per cent of the entire group of hemophilic diseases are due to PTC deficiency.

*Plasma thromboplastin antecedent deficiency* (PTA deficiency, hemophilia C) (p. 980) is a mild bleeding disease occurring in both sexes, transmitted by an autosomal dominant gene of high penetrance and variable expressivity. As a result, the disorder may occur in varying degrees, even within a single family.

*Hageman factor deficiency* (HF deficiency) is a hereditary defect in the coagulation mechanism discernible only *in vitro*, since patients with the defect have no clinical evidences of a bleeding tendency. It has been discovered in a few families by the finding of a prolonged coagulation time in either glass or siliconized tubes during the performance of routine preoperative coagulation tests on patients with no known tendency to bleed. The Hageman factor is apparently necessary along with AHG, PTC and PTA for thromboplastin formation. It is thought to be transmitted by an autosomal recessive gene.

*Labile factor deficiency* (parahemophilia) (p. 981) was described by Owren in 1947 in a female with menorrhagia. It is caused by absence or deficiency of the labile factor (factor V or accelerator globulin). Occurring in both sexes, its mode of transmission is not certain, but it is thought to be carried by a partially dominant gene. Deficiency of the labile factor causes prolongation of the one-stage prothrombin time, which is restored to normal by the addition of fresh plasma.

*Stable factor deficiency* (serum prothrombin conversion accelerator, SPCA, deficiency; proconvertin deficiency) is a hereditary hemorrhagic disorder apparently transmitted by an autosomal dominant gene. Recently a factor closely allied to it in activity has been segregated and named the *Stuart factor*. It appears to be inherited as an incompletely recessive characteristic of high penetrance.

Two types of *congenital hypoprothrombinemia* have been described by Quick. Type I is supposedly due to a deficiency of prothrombin caused by impaired enzymatic synthesis. In type II the total amount of circulating prothrombin is normal, but a postulated hereditary defect prevents the liberation of active prothrombin from the normal quanti-

ties of the inactive form. It has been suggested that the families described by Quick may be suffering from SPCA deficiency rather than from hypoprothrombinemia.

## AGAMMAGLOBULINEMIA

### (BRUTON'S DISEASE)

Hereditary defective synthesis of gamma globulin was discovered by Bruton (1952) in a boy who had had nineteen attacks of sepsis. A sex-linked recessive mutant gene transmits the disorder. A mother who is a carrier may pass the *disease* to half of her sons and the asymptomatic carrier state to half of her daughters. Failure of gamma globulin production is due to the absence of plasma cells in the hypoplastic lymphoid tissue characteristic of these patients. The hypoplasia of the adenoid tissue can be demonstrated roentgenographically and is of diagnostic help.

Children with the disorder are quite normal except for their inability to form antibodies to pyogenic bacteria (staphylococci, streptococci, pneumococci, meningococci and *Hemophilus influenzae*) or to such antigenic substances as diphtheria toxoid, typhoid vaccine, pneumococcal polysaccharides, heterologous tissues and the like. Absence of the appropriate isohemo-agglutinin from the blood, e.g., lack of anti-A antibodies in a child with a group B blood type, is another facet of this immunologic paralysis. The properdin system and complement activity of serum are unimpaired, and account for the normal resistance of these patients to infections with gram-negative bacteria. Unlike the hypersusceptibility to recurrent pyogenic infections, response to viral infections such as measles, mumps and poliomyelitis is normal with the development of lasting immunity. Paradoxically, circulating antibodies do not develop after immunization with viral vaccines. Smallpox vaccination has been done successfully without complication in at least ten children. However, four instances of vaccinia gangrenosa have occurred after vaccination of children with agammaglobulinemia. Administration of specific hyperimmune gamma globulin to two of the children helped arrest the life-threatening process. The failure of transplanted heterologous skin and other tissues to evoke an antibody response which in normal persons destroys these tissues permits their survival in agammaglobulinemic children.

Newborn infants with the defect have normal adult serum levels of gamma globulin,

FIG. 58. Physiologic hypogammaglobulinemia in the infant. (From Barrett and Volwiller: J.A.M.A., Vol. 164.)

averaging 900 mg. per 100 ml., derived entirely by passive transfer from the maternal circulation in the later months of gestation. Depletion of this store is complete at six months of age (Fig. 58). Increased susceptibility to infection occurs when the level of gamma globulin falls below 100 to 150 mg. per 100 ml., by two to four months of age.

Lymphopenia is a customary finding, and cyclic neutropenia occurs in some patients. During infectious episodes extreme polymorphonuclear leukocytosis (50,000 to 60,000 per cubic millimeter) is not unusual. Recurrent localized infection has led to such complications as bronchiectasis, impaired hearing and obstructive hydrocephalus. Many of the children have chronic rheumatoid arthritis.

The disease is suspected in a male child who has repeated bacterial infections or has a persistently positive Schick test or negative Widal test after adequate immunizations. Demonstration of a low level or absence of gamma globulin by immunochemical methods establishes the diagnosis; the zinc turbidity test and electrophoretic procedures are useful as screening procedures.

Prevention of infection is the major objective of medical management. Administration of prophylactic antibiotics and reasonable attempts at avoidance of infections are means to this end. Bacterial cultures are mandatory during illness as guides to appropriate intensive antibiotic therapy. Monthly intramuscular injections of 0.7 ml. of gamma globulin (solution) per kilogram of body weight will maintain minimal but effective serum levels of 100 to 150 mg. per 100 ml. The initial

dose of gamma globulin (priming dose) is twice the maintenance dose, or 1.4 ml. per kilogram; some patients require higher maintenance doses.

#### BETA-2-GLOBULIN DEFICIENCY ASSOCIATED WITH IMMUNOLOGIC PARALYSIS

Recently the presence of a disturbance which duplicated the findings of agammaglobulinemia was reported in a four-year-old boy with normal serum gamma globulin levels. However, the absence of two specific beta-2-globulins was demonstrable, and the condition is proposed as a new molecular disease.

#### HAPTOGLOBIN DEFICIENCY

Hereditary deficiency of the haptoglobins, the plasma beta-2-globulins which bind free hemoglobin, has been suggested as an explanation for some instances of hemoglobinuria. Although the amount of hemoglobin which the haptoglobins bind is the same (125 mg. per 100 ml.), there are variations in the types of haptoglobin in different normal persons. A given person may have either one, three or four distinct haptoglobins, depending upon whether he is homozygous or heterozygous for a single pair of allelomorphous genes.

Increased hemolysis of red blood cells during strenuous exercise is a recognized phenomenon in defective persons. Usually the released hemoglobin is not excreted by the kidney, because of its union with haptoglobin. However, in persons with *march*

*hemoglobinuria*, hemoglobin appears in the urine after a long walk or race. Decreases or absence of haptoglobin appears to be the hereditary basis for this benign type of hemoglobinuria.

## HEREDITARY CERULOPLASMIN DEFICIENCY

Ceruloplasmin, a blue-colored alpha-2-globulin containing eight copper atoms per molecule, comprises 0.5 per cent of the total plasma proteins. The average normal concentration is 24 mg. per 100 ml. (range, 16 to 33 mg.). Low levels are found in newborn infants, presumably owing to immaturity of the synthetic mechanisms, and in patients with active nephrosis, in which ceruloplasmin is lost in the urine. In *Wilson's disease* (hepatolenticular degeneration, p. 1098), a hereditary disorder transmitted by an autosomal recessive gene, low levels of ceruloplasmin, averaging 5 mg. per 100 ml. (range, 0 to 14 mg.), are apparently responsible for the abnormal accumulations of copper in tissues. It appears likely that the primary genetic defect in *Wilson's disease* is in the

synthesis of ceruloplasmin. By permitting increased absorption of ingested copper and increased deposition in tissues, the ceruloplasmin deficit is responsible for injury to organs most susceptible to damage by copper, i.e., the brain, liver and kidneys. Although the mechanism of copper intoxication is not clear, the clinical features of *Wilson's disease*, including the Kayser-Fleischer corneal ring, are reflections of disturbances in the organs with an abnormally high copper content.

## ANALBUMINEMIA

Total absence of serum albumin as a genetic defect was reported by Bennhold (1954) in a German woman aged twenty-five years, and her thirty-three-year-old brother. Another sister and 150 members of the family who were studied were normal in this respect. Except for slight edema of the ankles after an arduous day's work, the lack of clinical findings is remarkable. An American woman with the same defect is under study. Apparently many of the functions of albumin are taken over by globulin fractions, which are increased in concentration.

## Defective Hemoglobin Synthesis

### ABNORMAL HEMOGLOBINS

These disorders, described elsewhere, are inborn errors in synthesis of the globin moiety of hemoglobin. Following Pauling's fundamental discovery of an abnormal hemoglobin (S) in "sicklers" (1949), numerous other hemoglobin variants have been identified (hemoglobins S, C, D, E, G, H, I, J, K, L, M, N, O, P, Q and Bart's).

The genes which control the formation of hemoglobin are found at three chromosomal loci. Various combinations of different genes at these sites form the numerous genotypes which are manifested clinically as the abnormal hemoglobin diseases and traits.

There is a single locus for the gene controlling normal hemoglobin (A) production and the mutant alleles responsible for the presence of the abnormal hemoglobins. The mutant genes are incompletely recessive, so that homozygous subjects differ from heterozygotes in the magnitude of their abnormality, rather than in the usual all-or-none fashion of completely recessive traits. This is well exemplified by persons with hemoglobin S;

the more serious sickle cell disease is a manifestation of homozygosity, whereas the heterozygote has less abnormal hemoglobin and has only the sickle cell trait. The finding of two abnormal hemoglobins in the same person, e.g., S and C or S and D, is evidence of heterozygosity for both genes.

The genes which control the *rate* of synthesis of normal hemoglobin reside in a second site, the so-called thalassemia locus. Homozygosity for the mutant gene in this location causes *thalassemia major*; the phenotype for heterozygosity is the milder trait, *thalassemia minor*. Double heterozygosity for the thalassemia major and the thalassemia trait is a well recognized occurrence.

Fetal hemoglobin, normally found in the fetus and young infant, is represented by a gene situated at a third focus. Interference with the formation of normal adult hemoglobin (A), e.g., in subjects with abnormal hemoglobins, evokes resumption of production of fetal hemoglobin. Thus patients with *sickle cell anemia* and *thalassemia* have circulating hemoglobin F.

The hemoglobin of sickle cell anemia

differs from hemoglobin A by the replacement of a glutamic acid residue by a valine residue in the polypeptide chain of 300 molecules of

amino acid which forms the protein. In hemoglobin C disease a lysine residue replaces the glutamic acid residue.

Defective Amino Acid Metabolism

ERRORS IN PHENYLALANINE AND TYROSINE METABOLISM

Congenital defects in the intermediary metabolism of the amino acids phenylalanine and tyrosine are the bases for a number of inter-

esting clinically defined disorders. Phenylalanine is an essential amino acid; i.e., the body is unable to manufacture it. Tyrosine may be derived by oxidation of phenylalanine in the body and is thus termed a dispensable amino acid. The location of the chemical de-

FIG. 59. Phenylalanine-tyrosine intermediary metabolism in man, indicating relation of inherited defects to specific chemical reactions.

fects associated with the inherited errors of phenylalanine-tyrosine metabolism is indicated in Figure 59.

### ALCAPTONURIA

Alcaptonuria is a rare disorder of phenylalanine-tyrosine metabolism characterized by the urinary excretion of homogentisic acid (also known as alcapton or 2,5-dihydroxyphenylacetic acid). More than 200 cases have been recorded. In the great majority of patients the disorder is transmitted by a single autosomal recessive gene. It is estimated that there are five alcaptonurics per million persons, and that one in 200 people is a heterozygous carrier of the recessive gene. It occurs in both white and Negro races.

Urine containing homogentisic acid becomes dark on standing, owing to oxidation and polymerization. In infants the diaper may be stained, leading to detection of the defect, which is otherwise asymptomatic. The darkness of the stain increases with continued exposure to air, and a dried diaper will show a pitch-black stain. The slow accumulation of a black polymer of homogentisic acid in the cartilage and other mesenchymal tissues produces a black discoloration of the cheeks, nose, sclerae and ears in middle-aged patients. This is termed *alcaptonuric ochronosis*. Degeneration of cartilage in which the pigment is concentrated leads to arthritis in about half of the older alcaptonurics.

The metabolic block in alcaptonuria is due to hereditary absence from the body tissues of homogentisate oxidase (see Fig. 59). As a consequence of the enzymatic deficit, the catabolism of tyrosine is arrested at the stage of homogentisic acid, which is rapidly excreted in the urine by the combined processes of glomerular filtration and renal tubular secretion. Alcaptonuria occurs in scorbutic guinea pigs, but, unlike the human disorder, this induced defect is abolished by administration of ascorbic acid.

The addition of alkali accelerates the spontaneous darkening of alcaptonuric urine. The urine has reducing properties, giving a positive reaction with Fehling's or Benedict's reagent and reducing an ammoniacal solution of silver nitrate in the cold. If a dilute solution of ferric chloride is allowed to drop into urine containing homogentisic acid, a fleeting deep blue color appears in the path of the drops. A rapid test for alcaptonuria is the blackening of sensitized photographic paper by a drop of strongly alkaline alcaptonuric urine. A positive Millon test occurs with

alcaptonuric urine. The failure of alcaptonuric urine to ferment yeast, to form osazones, to react with the specific glucose enzyme test papers or to rotate polarized light differentiates it from urine containing glucose. The dark urine of phenol poisoning and the melanuria associated with melanotic tumors have no reducing properties.

There is no treatment which will correct the enzymatic block. The fact that urinary excretion of homogentisic acid varies directly with protein intake, disappearing during starvation, is no indication for rigid dietary restriction of protein in view of the relative harmlessness of alcaptonuria in children. Corticosteroid therapy has a beneficial effect on the arthritis of older alcaptonurics.

### PHENYLKETONURIA

Phenylketonuria (phenylpyruvic oligophrenia, Fölling's disease, phenylpyruvic amentia, imbecillitas phenylpyruvica) (p. 1131) is a rare disorder characterized by mental deficiency and the excretion of phenylketones. Its incidence is estimated to be about one in 40,000. Affecting both sexes equally, it is transmitted by a recessive gene. About one per hundred of the population is an asymptomatic (heterozygous) carrier of the mutant gene.

Deficiency of the hepatic enzyme phenylalanine hydroxylase, which normally transforms phenylalanine to tyrosine, is the primary biochemical defect in phenylketonuria. Normally the portion of dietary phenylalanine in excess of the organism's requirement for protein formation is converted to tyrosine and utilized or degraded to acetoacetate. Inability to form tyrosine leads to a piling up of phenylalanine in the body fluids; adaptive mechanisms of alternative metabolic pathways for the disposal of phenylalanine account for the formation of the phenylketone bodies (phenylpyruvate, phenyllactate, phenylacetate and phenylacetyl glutamine), which are excreted in the urine. The existence of a secondary metabolic channel which apparently transforms 10 per cent of excess phenylalanine to ortho-tyrosine was first indicated by the finding of the compound ortho-hydroxy-phenylpyruvic acid in phenylketonuric urine.

The abnormal biochemical environment of the brain, created by high concentrations of phenylalanine and its derivatives, is responsible for mental deficiency and other neurologic abnormalities. The precise mechanism by which the nervous system is injured is not clear. Cutaneous abnormalities, such as ex-

cessive oiliness, scaliness and eczematoid lesions, which occur in one third of phenylketonuric children may have a pathogenesis similar to that for brain damage, and the high concentrations of phenylalanine are responsible for the "mousey" odor of the urine and the musty body odor of the unwashed body.

Failure of formation of melanin pigments because of an inadequate supply of tyrosine may account for the finding that 90 per cent of phenylketonuric children are blue-eyed blondes with fair skins. The rapid darkening of the skin, hair and eyes, which often occurs after the institution of a phenylalanine-restricted diet containing added tyrosine, supports this view.

Infants with phenylketonuria appear to be normal at birth and during the neonatal period. Plasma phenylalanine levels are normal in newborns, and phenylpyruvic acid does not appear in the urine until plasma phenylalanine rises to the level of 15 mg. per 100 ml. This may occur as early as six days and as late as thirty-five days. At this time progressive brain damage begins, reaching a maximal upper limit at two to three years of age. Diets low in phenylalanine (Lofenalac and Ketonil) begun during the neonatal period can prevent the development of mental deficiency. Initiation of dietary treatment before the age of two to three years may arrest the progress of brain damage; it does not appear to reverse the process. In older phenylketonuric children there is no apparent improvement of mental deficiency on such diets. However, improved attention spans, calmer behavior, subsidence of neurologic signs and improvement in previously abnormal electroencephalograms indicate the salutary effect of the avoidance of exposure of the maximally damaged brains of these children to phenylalanine.

As an aid to premarital genetic counseling, it appears that it may be possible to detect the asymptomatic heterozygous carrier of phenylketonuria by laboratory means. The fasting plasma phenylalanine levels are higher than usual, and there is a higher and more sustained rise in the plasma level following a test dose of phenylalanine in heterozygous persons than in normal ones.

#### TYROSINOSIS

In 1927 Medes discovered the only known instance of this error in tyrosine metabolism in an adult believed to have myasthenia

gravis. The presence of parahydroxy-phenylpyruvic acid in the urine indicated that catabolism of tyrosine was blocked at the level of its deamination product. Progressive increases in protein or tyrosine intake resulted in the appearance in the urine of tyrosine initially, then parahydroxy-phenyl-lactate and finally 3:4 dihydroxyphenylalanine. There were no apparent symptoms related to the metabolic defect.

Premature infants (p. 310) receiving a high protein diet without vitamin C have tyrosyluria, in that they excrete parahydroxy-phenylpyruvate and parahydroxy-phenyl-lactate. Administration of vitamin C abolishes this metabolic impairment. Since the liver is the site for the metabolism of parahydroxy-phenylpyruvate, it is not surprising that patients with liver disease spontaneously excrete small amounts of this compound.

#### ALBINISM

Albinism, or absence of cutaneous pigments, exists in two forms. Total albinism (*albinismus totalis*) is characterized by unpigmented skin, hair, eyebrows, eyelashes and eyes. The less common partial albinism (*albinismus conscriptus*) has two features: the white forelock and piebaldness, i.e., irregular, well defined pigment-free areas of skin, usually of the extremities and anterior trunk and abdomen. Total albinism is most often a recessive trait, whereas the partial form is transmitted by a dominant gene, a finding which conforms to the general rule in human heredity that the more severe form of a mutation tends to be recessive and the milder form, dominant. A moderate preponderance of male albinos may be indicative of a partial sex-linked inheritance.

Total albinism occurs in all races, varying in incidence from 0.7 per cent in the San Blas Indians of Darien to one in 100,000 in France. In the United States the rate is approximately one in 20,000; one in seventy is the estimated asymptomatic (heterozygous) carrier rate.

In addition to the extremely white skin and fine silky hair, albinos have numerous ocular abnormalities. Although traces of pigment may occur on the uveal borders, it is absent from the iris, sclera and fundus, and the eye appears pink and translucent. Refractive errors, strabismus, nystagmus and photophobia are common findings. In general, albinos do not differ in range of intelligence and mentality from the rest of the popula-

tion, even though there appears to be a slightly higher incidence of mental deficiency among them. The white forelock of hair may be the sole manifestation of the defect in some families; it is more frequent than piebaldness alone.

The albino has the normal number of pigment-forming cells (melanocytes) in the basal layer of the skin. Owing to the inherited deficit of the copper-containing enzyme tyrosinase, the cells do not form melanin. The pigmented skin areas of piebald human beings and animals contain tyrosinase.

There is no treatment for albinism. Preventive measures may be necessary against the harmful effects of sunlight on the unpigmented skin and eyes. Unable to tan, the skin is constantly vulnerable to the "burning" rays of the sun. Tinted glasses are required for relief of photophobia.

## HEREDITARY CLINICAL SYNDROMES OF TUBULAR INSUFFICIENCY

The concept of hereditary molecular disease extends the meaning of Garrod's term, the inborn error of metabolism. Pauling's conceptual designation now encompasses hereditary control of specific functional substances and mechanisms other than enzymes. For example, in cystinuria the genetically determined enzyme-like factor controlling renal tubular transport of certain amino acids is thought to be in the molecular category. In this sense, cystinuria and a number of other inherited renal tubular dysfunctions

- D. Glucose, phosphate, amino acids (mild), impaired urinary acid-base regulation and organic aciduria
  1. Syndrome of buphthalmos, cataracts, mental retardation, resistant rickets, hyperchloremic acidosis and organic aciduria

may be considered molecular diseases. A convenient grouping of the recognized clinical syndromes of tubular dysfunction is given in Table 47.

**Hereditary Defects of the Renal Tubules Involving a Single Function.** *Defective reabsorption of glucose.* *Renal glycosuria* is an uncommon benign disorder, usually inherited as a dominant trait (p. 1020).

*Defective reabsorption of water.* *Nephrogenic diabetes insipidus* (p. 1156) is distinguished from the type due to hormonal deficiency of pituitary origin by its lack of response to injected vasopressin because of the refractoriness of the renal tubules to the action of the antidiuretic hormone. In one family the disorder was inherited in a recessive sex-linked fashion, and only males were affected. In another lineage an affected female indicated that the gene was an autosomal recessive, and in a third family, heterozygous female carriers had mild diabetes insipidus.

*Defective reabsorption of inorganic phosphate.* *Pseudohypoparathyroidism (the Seabright bantam syndrome)* is due to hereditary failure of the renal tubules to respond to parathyroid hormone, an end-organ failure. The increased tubular reabsorption of phosphate which occurs in the absence of hormonal inhibition leads first to hyperphosphatemia and ultimately to hypocalcemic tetany (p. 1176).

*Renal hypophosphatemia or vitamin D-resistant rickets* is a relatively common congenital hereditary disease, transmitted by a sex-linked dominant gene (p. 1221).

*Defective acidification of the urine.* *Renal tubular acidosis* is a clinical syndrome due to impairment of the renal tubular mechanism for acidifying the urine (p. 1223).

*Defective reabsorption of purines (xanthine, uric acid).* *Simple xanthuria* is apparently due to deficient reabsorption from the glomerular filtrate, but the possibility of a metabolic defect involving xanthine has not been eliminated. Xanthine, a precursor of uric acid, is excreted in the urine in abnormal amounts, and uric acid is virtually absent from the plasma and urine.

*Hereditary hyperuricemia* is transmitted by a dominant autosomal gene with different degrees of penetrance in the two sexes. Elevated plasma uric acid levels occur in 84 per cent of males with the abnormal gene, but in only 12 per cent of the females. Gout also occurs earlier and about twenty times

more frequently in hyperuricemic men than in similarly affected women. Primarily an adult disorder, gout rarely occurs in children.

*Defective reabsorption of amino acids (amino-acidurias).* Cystinuria is discussed later.

*Simple glycinuria* is a unique amino-aciduria in that there is resorptive deficiency of only one amino acid, glycine. The defect is transmitted by a dominant gene. In a family of four affected persons, three formed calcium oxalate stones which contained 0.5 per cent of glycine. All showed glycinuria. They were otherwise asymptomatic and normal in growth.

*Beta-aminoisobutyric aciduria* is present in 5 to 10 per cent of the population in certain areas of England and Italy which have been studied. Affected persons are asymptomatic, but have a daily excretion of 100 to 300 mg. of beta-aminoisobutyric acid in contrast to 10 to 40 mg. in other members of the population. The defect is transmitted by a single recessive gene.

*Hereditary Double Functional Defects of the Renal Tubules. Combined glycosuria and phosphaturia.* This is a type of vitamin D-resistant rickets in which hypophosphatemia and rickets exist in combination with renal glycosuria. Dent has described four instances of this syndrome.

*Combined glycosuria and amino-aciduria.* This syndrome has been recorded in three generations of one family, including a pair of twins. Although the affected subjects were asymptomatic, generalized massive amino-aciduria and moderate glycosuria were present.

*Combined phosphaturia and amino-aciduria.* This is a variant of hypophosphatemic vitamin D-resistant rickets. Effective treatment of the rickets with massive doses of vitamin D also causes suppression of the amino-aciduria. This factor has been interpreted as evidence for a common tubular reabsorptive pathway for phosphates and amino acids. However, the demonstration of depressed glomerular filtration during such therapy may be the explanation for the decrease in amino-aciduria.

*Hereditary Multiple Functional Defects of the Renal Tubules. Glycosuria, phosphaturia, amino-aciduria, the de Toni-Debré-Fanconi syndrome.* De Toni first suggested that this triple defect, observed by him in a child, might be due to tubular dysfunction. The disorder, cystinosis, for which the names of Abderhalden, Kaufmann and Lignac are used in Europe, is included by many in this syndrome and will be so considered here under the term "de Toni-Fanconi syndrome with cystinosis."

*Glycosuria, phosphaturia, amino-aciduria, impaired acidification of urine and organic aciduria.* In a small number of patients with a syndrome of buphthalmos, cataracts, congenital rickets, hyperchloremic acidosis and mental deficiency in addition to many of the urinary findings of the de Toni-Fanconi syndrome, an appreciable excretion of organic acids is encountered (p. 1222).

## MOLECULAR DISEASES INVOLVING CYSTINE AND GLUTATHIONE

The sulfur-containing amino acid cystine is identified with the molecular diseases cysti-

nuria and cystinosis. These are entirely unrelated disturbances, due to different genetic defects, and are not the phenotypic variants of a single genic mutation they were once thought to be. Hereditary alteration in the metabolism of the tripeptide glutathione (glutamyl-cysteinyl-glycine) in the erythrocytes is responsible for certain drug- and toxin-induced hemolytic anemias.

### CYSTINURIA

Cystinuria is an inherited anomaly of renal function with massive urinary excretion of cystine, lysine, arginine and ornithine due to defective tubular reabsorption of these amino acids from the glomerular filtrate. Average daily excretions of 0.73 gm. of cystine, 1.8 gm. of lysine, 0.83 gm. of arginine and 0.37 gm. of ornithine reported in five patients are representative of the daily urinary losses. Cystine, because it is the least soluble and forms conspicuous crystals and calculi, was the only one of the four amino acids recognized until recently. Failure to appreciate the presence of the other three amino acids was responsible not only for the name of the disorder, i.e., cystinuria, but also for the erroneous assumption that it was a block in the intermediary metabolism of the sulfur-containing amino acids, cystine, cysteine and methionine. Two types of cystinuria have been differentiated genetically. In two thirds of the families the defect is transmitted as a recessive trait. The abnormal homozygotes excrete abnormal amounts of all four amino acids and form cystine stones at some time during their lives. No abnormality is discernible in the heterozygous "carriers." This condition has been termed *recessive cystinuria*.

In the second and smaller group of families the abnormal genes for cystinuria are only partially recessive. Here also the abnormal homozygotes excrete large amounts of the four amino acids and form renal stones. Clinically, they are indistinguishable from the genotypically similar members of families with recessive cystinuria. Heterozygous persons in this group, however, are not normal, for they excrete moderate quantities of cystine and lysine, and little or no arginine and ornithine. They do not form calculi except in the rare instance when the level of cystine excretion is high. The milder tubular reabsorptive defect in this second type of family is designated "*incompletely recessive cystinuria*."

The estimated incidence of cystinuria with

renal stone formation varies from 1:40,000 to 1:200,000. Nonstone-forming heterozygous excretors of cystine and lysine are more numerous (1:600).

Cystine crystals are clear colorless hexagons with somewhat unequal sides and are characteristically different from any other urinary deposit. Urine containing cystine liberates hydrogen sulfide on decomposition. Stasis and infection in the urinary tract predispose the cystinuric patient to calculus formation. Acidity and concentration of the urine may precipitate crystals of sparingly soluble cystine (1:9000 in water). The elaboration of more concentrated urine during sleep at night may initiate stone formation. Cystine calculi are usually white, but occasionally are yellow. When kept for years, the color changes to green. The stones cast dense roentgenographic shadows.

Responsible for less than 1 per cent of all adult urinary calculi, cystine stones account for a larger proportion of those encountered in infants and children. The diagnosis is established by detection of cystine crystals in acidified urine and the demonstration of abnormal quantities of cystine, lysine, arginine and ornithine by paper chromatography. Siblings of a cystinuric patient should be screened for the defect, since there is a one-in-four probability that any one of them may be affected.

Maintenance of a liberal fluid intake to ensure a constant and copious flow of dilute urine (above 2 cc. per minute) may minimize the tendency to stone formation. Eradication of urinary tract infection and stasis is important. At pH values above 7.6 the solubility of cystine in urine increases significantly. Whether the constant intake of the large doses of alkali needed to maintain such high pH values is practical appears doubtful. Of even more dubious value are attempts to dissolve cystine stones by such therapy. Cystine excretion increases on a high protein diet, but severe restriction of protein intake is inadvisable as a therapeutic measure in infants and children. The excretion of lysine, which is lost in larger quantities than cystine, may produce a negative balance for this essential amino acid with deleterious effects on growth.

**CYSTINOSIS (DE TONI-FANCONI SYNDROME WITH CYSTINOSIS, ABDERHALDEN-KAUFMANN-LIGNAC DISEASE)**

Cystinosis, which was first recognized at autopsy by Abderhalden and Kaufmann in 1903,

was established as a clinical entity by Lignac in 1924. It is characterized by the clinical pattern of the de Toni-Fanconi syndrome, i.e., stunted growth, resistant hypophosphatemic rickets, glycosuria, acidosis, generalized amino-aciduria, organic aciduria, combined with the presence of cystine crystals in various tissues of the body. With one possible exception, in which the inheritance appeared to be dominant, the disorder seems to be transmitted by a recessive gene. The adult variety of the de Toni-Fanconi syndrome is inherited as a dominant character.

The pathogenesis of the major abnormalities of the de Toni-Fanconi syndrome with cystinosis is not readily explained. The tubular dysfunctions characteristic of the de Toni-Fanconi syndrome by itself may occur in a number of known intoxications (lead poisoning) and can also be produced in rats by injection of maleic acid. Accordingly, it has been proposed that the renal defects in patients with cystinosis may be due to obscure cystine intoxication, especially since it has nephrotoxic activity. Another theory assumes a metabolic abnormality which prevents utilization of cystine by the cells, so that it is deposited as crystals. Before entering the metabolic pathway of the sulfur-containing amino acids, cystine normally undergoes reduction to cysteine. A deficiency of the specific enzyme, cystine reductase, is postulated to be the basic hereditary molecular defect in this hypothesis.

The characteristic pathologic finding in patients with cystine disease is the deposition of cystine in the reticuloendothelial system, especially apparent in the liver, spleen, lymph nodes and bone marrow. In the liver small foci of proliferated Kupffer cells containing cystine are conspicuous. Cystine deposits have been noted in the renal tubular cells. Vacuolization of tubular cells, probably due to potassium depletion, may be seen. Darmady has demonstrated a striking lesion in the most proximal portion of the tubule; narrowing due to atrophy produces a "swan's neck" appearance at this site. There is no evidence that this is a genetic defect. In cases of longer duration extensive glomerular changes and arteriolar lesions resembling chronic glomerulonephritis are seen.

Clinically, these infants usually appear normal at birth and during the early months of life. In the latter part of the first year or during the second year, growth becomes retarded. Anorexia, vomiting and constipation are conspicuous early manifestations. A

FIG. 60. Cystine crystals of ammoniacal spleen extract.  $\times 180$ . (Looser in *Ann. paediat.*, Vols. 162, 163.)

preference or even craving for meat and other protein foods is often noted. Polyuria, polydipsia and nycturia are frequent. Extreme thermolability with a tendency to high fever without apparent cause is present as the disease progresses. Dehydration and intoxication develop in response to mild infections. Intense photophobia may be a troublesome complaint. The bones at first show osteoporotic changes, upon which the changes of infantile rickets responding to vitamin D may become superimposed. With the gradual development of renal failure the bones show the changes of renal rickets (i.e., osteitis fibrosa cystica or renal hyperparathyroidism). Terminally there may be elevation of the blood pressure, but eyeground changes are usually absent. Enlargement of the liver, but not of the spleen, is seen in the final stages of the disease. The stunting of growth may be so extreme as to be classed as dwarfing.

The duration of the illness varies. It may progress rapidly, and death may occur as early as five months of age. Few children live beyond eight years of age.

The urine may be acid or alkaline. Early in the illness, polyuria and dilute urine are the result of deficient tubular reabsorption of water; later, as glomerular failure occurs, the specific gravity becomes low and fixed. Mild albuminuria and pyuria may occur. Glycosuria varies; slight or absent at first, it may rise to a level of 20 gm. per day. Phosphaturia is marked. Impaired tubular capacity to exchange intracellular hydrogen ions for urinary base causes loss of bicarbonate. Accordingly, the ammonia content of the urine may seem high, but is actually low when judged

by the severity of the acidosis. Considerable amounts of potassium are lost in the urine, in part by excretion with bicarbonate, but in larger measure through distal tubular secretion of potassium as an exchange for urinary sodium.

Paper chromatographic studies show a generalized amino-aciduria which varies in different patients, but has a constant pattern in the individual patient. Glycine is excreted in largest amount. Smaller, but as much as twenty times normal, amounts of threonine, serine, alanine, tyrosine and lysine are lost, as are also such essential amino acids as phenylalanine, valine, methionine, leucine and isoleucine. The amounts of cystine lost are far below those which occur in cystinuria. Amino-aciduria and glycosuria may disappear when renal failure occurs. Increased amounts of urinary organic acids occur and seem to be due to the same tubular reabsorptive defect which causes amino-aciduria.

The inorganic phosphate level of the blood is low during the early stages of the disease, but increases along with the nonprotein nitrogen as renal function fails. Concomitantly, serum calcium levels decrease and may reach tetanic levels. Phosphatase values may be low if active rickets is present; otherwise they tend to be normal. Serum protein concentration is usually not greatly altered. During illness the often low serum potassium level may decrease rapidly to still lower levels productive of clinical hypokalemia. Hyperchloremic acidosis is typically present. There are no characteristic hematologic changes, but anemia and bleeding phenomena occur with renal failure.

Cystine crystals, if present, are demonstrable in the cornea by slit lamp microscopy or in conjunctival scrapings. Bone marrow examination and lymph node biopsy are valuable diagnostic procedures in the search for crystals of cystine.

Therapy is unsatisfactory; death is characteristically due to uremia. Temporary amelioration is possible by the use of a basic ash diet supplemented with moderately high doses of vitamin D. Administration of a citrate solution (p. 1224) such as that of Shohl or Albright with added potassium chloride is advisable for control of the acidosis and hypokalemia.

#### DISORDERED GLUTATHIONE METABOLISM

Ingestion of primaquine, sulfanilamide, acetanilid, nitrofurantoin, naphthalene and fava

beans, in amounts nontoxic for most persons, causes hemolytic anemia in certain persons who are otherwise normal. Such persons have a genetically determined defect in the metabolism of glutathione in their erythrocytes. The specific molecular defect is a deficiency of the enzyme glucose-6-phosphate dehydrogenase, which is normally involved in the maintenance of glutathione in a reduced state. Reduced glutathione is an important source of free sulfhydryl groups (-SH), which are required by a large number of cellular enzymes and coenzymes.

This hereditary biochemical deficit has been found in 4.6 per cent of a random sample of 305 subjects; it was more than five times as common among healthy American Negroes as among healthy whites. It is transmitted as a recessive trait, which is apparently sex-linked and sex-modified.

Another genetic biochemical defect has been shown to be the basis for hypersusceptibility to the action of succinylcholine, a drug used as a muscle relaxant during anesthesia.

## INHERITED DISORDERS INVOLVING TRYPTOPHANE

**Metabolism of Tryptophane.** The essential amino acid tryptophane and a number of its derived compounds have important biologic activities. Skatole and indole, two foul-smelling substances, are products of bacterial putrefaction of tryptophane in the large intestine. The participation of pyridoxine in the metabolism of tryptophane was first indicated by the finding of xanthurenic acid, an unusual tryptophane metabolite, in the urine of rats with deficiency of vitamin B<sub>6</sub>. The discovery that pyridoxine deficiency was the cause of a convulsive disorder in infants was prompted by this observation in rats. Xanthurenic acid has been demonstrated in the urine of affected infants, and the convulsions are believed to be a result of disordered cerebral tryptophane metabolism. The detection of a disturbance in tryptophane metabolism in association with a hereditary anemia in infants has an analogue in the anemia exhibited by pyridoxine-deficient dogs. Unlike the deficient rat, the anemic dog does not excrete xanthurenic acid.

Serotonin (5-hydroxytryptamine or 5-HT) is an amine derived from a tryptophane metabolite, 5-hydroxytryptophane. It has potent pharmacologic actions, and as a central neurohumoral agent it is apparently involved

in cerebral function. First isolated from platelets in 1951, it was identified as a vasoconstrictive compound. The chromaffin ganglionic cells of the gastrointestinal tract and cerebral cells, acting as endocrine organs, are believed to secrete it. Serotonin-secreting carcinoid tumors in adults arise from the argentaffin cells of the gastrointestinal tract and cause a pattern of clinical findings which indicate the diverse activities of 5-HT, i.e., connective tissue damage evident as arthritis and endocardial sclerosis, intestinal hypermotility causing diarrhea, vasomotor disturbances such as flushing and hypotensive episodes, acute dyspnea due to bronchoconstriction, and azotemia from reduced glomerular filtration caused by constriction of renal arterioles. The resemblance of the cardiac lesion in these patients to endocardial sclerosis in infants has suggested a similar etiology for it. Increased urinary excretion of a catabolite of 5-HT (5-hydroxyindole acetic acid, 5-HIAA) has also been observed in adults with the celiac syndrome. A simple chemical test for detection of the compound is available.

Serotonin and the enzymes which form and degrade it are most highly concentrated in the hypothalamus. A current concept of its functional role in the brain is that it acts as a chemical mediator at the synaptic junctions in the parasympathetic centers. A similar action is proposed for norepinephrine in the sympathetic centers. The autonomic, motor and psychic responses to drugs such as reserpine and chlorpromazine are attributed to their effect on these two chemical mediators.

### DISORDERED TRYPTOPHANE METABOLISM IN CONGENITAL HYPOPLASTIC ANEMIA

Congenital hypoplastic anemia is a rare chronic anemia due to faulty formation or maturation of erythrocytes by an otherwise normally functioning bone marrow (p. 934). Anthranilic acid has been identified in the urine of ten patients. The nature of the disturbance in tryptophane intermediary metabolism and its relationship to the anemia are obscure, especially since there is no demonstrable deficiency of nicotinic acid in these patients (Fig. 61, pathway B).

### MENTAL DEFECT (AUTISM) AND DISORDERED TRYPTOPHANE METABOLISM

A defect in tryptophane metabolism has been observed in a child with autistic behavior and in a normal younger sibling; the possi-

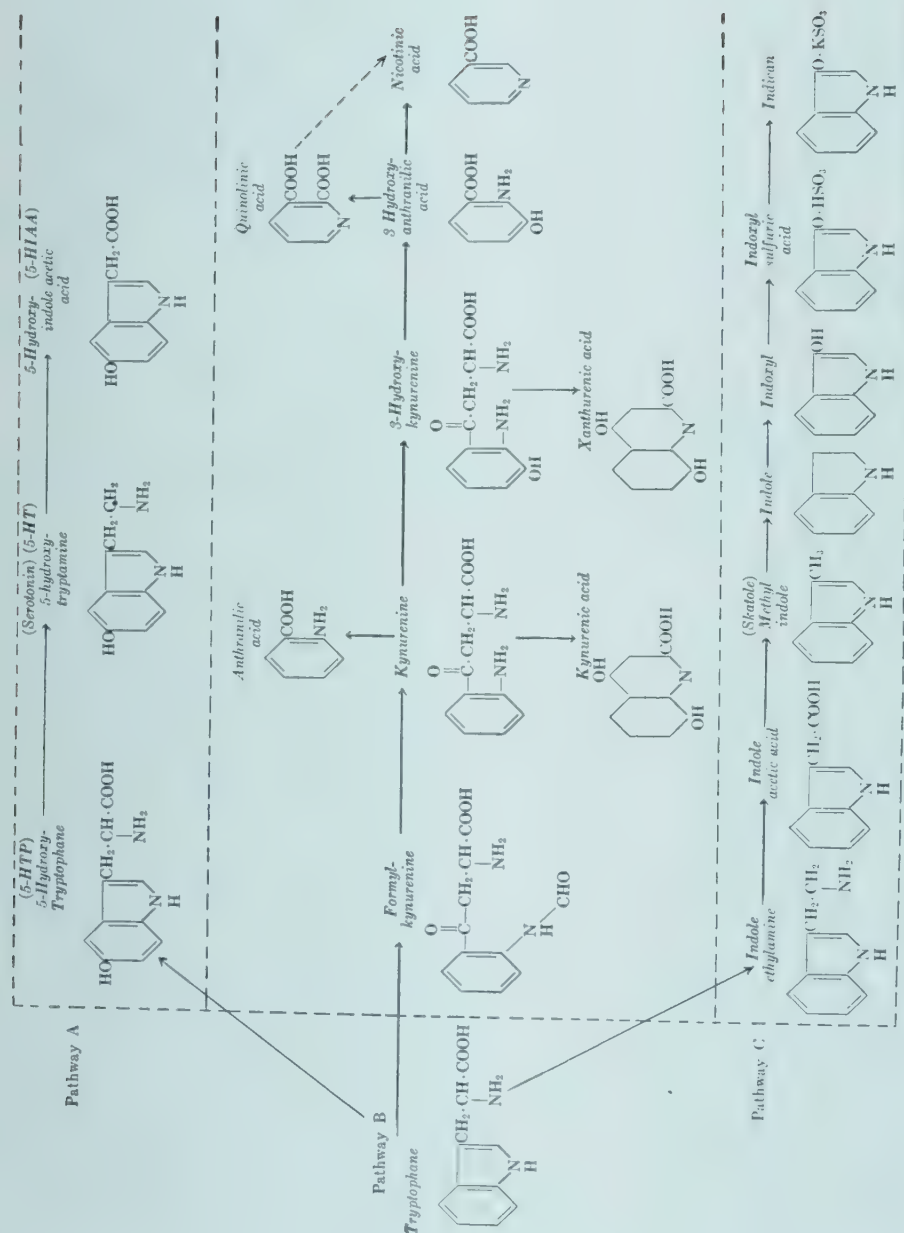

FIG. 61. Intermediary metabolic pathways for tryptophane. A, Serotonin formation and degradation (oxidative). Since the brain cannot utilize tryptophan directly, it uses the oxidation product 5-hydroxytryptophane. The brain enzyme 5-hydroxytryptophan decarboxylase converts 5-HTP to serotonin, which is metabolized by the enzyme monamine oxidase to 5-HIAA. Excessive formation of 5-HIAA results in excretion in the urine, where it may be detected chemically as an evidence of increased serotonin turnover.

B, Conversion of the indole ring of tryptophane to the pyridine ring of nicotinic acid. The first step in this metabolic pathway is the formation of a pyridine ring by enzymatic splitting of the indole ring. Formyl kynurenine is then hydrolyzed to kynurenine, and in a straight course this is converted to nicotinic acid (the aromatic pathway of tryptophane metabolism). In the rat a second pathway, the quinoline channel, is present, and kynurenine acid is formed from kynurenine. Anthranilic acid is an intermediate metabolite in man and has been found in the urine of infants with congenital hypoplastic anemia. Pyridoxine deficiency causes the appearance of xanthurenic acid in the urine of the rat and man. Although quinolinic acid is not on the straight route to nicotinic acid synthesis, it can apparently be partially converted.

C, Formation of indole in the intestinal tract by bacterial putrefaction. After decarboxylation all the compounds up to indole may be absorbed from the intestinal tract and, after conjugation in the liver, Indican is produced by conjugation with sulfuric acid.

bility of defective serotonin formation has been postulated.

#### **HARTNUP DISEASE**

Hartnup disease, first termed H disease to keep anonymous the affected English family after whom the disease is named, is a recently discovered hereditary molecular disease in which there is a block in the intermediary metabolism of tryptophane.

Clinical manifestations of cutaneous photosensitivity are seen early in most affected children. Unprotected skin areas become rough and red after moderate exposure to the sun. With greater exposure a rash, identical with that of pellagra, develops, together with a neurologic syndrome which is unlike the peripheral neuritis of pellagra. The neurologic findings consist of signs of cerebellar ataxia with traces of involvement of the pyramidal tracts. During the course of a febrile illness, ataxia may develop without a rash. The clinical course is variable; severe cutaneous and nervous disturbances may alternate with periods of complete remission over many years. Mental deficiency is a late occurrence and progresses slowly. Remission of the disorder occurs spontaneously in most patients, usually in adult life. However, administration of large doses of nicotinamide appears to facilitate regression of symptoms.

Massive amino-aciduria is present during the entire lifetime of patients; the pattern of excretion of individual amino acids is characteristic in that proline metabolism is not disturbed in contrast to the urinary excretion of it in the generalized amino-acidurias, such as the de Toni-Fanconi syndrome. Furthermore, there are no alterations in the excretion of hydroxyproline, methionine, arginine and taurine. There is excessive urinary loss of alanine, serine, asparagin, glutamine, valine, leucine, isoleucine, phenylalanine and tryptophane, and moderate losses of cystine, lysine and glycine. Plasma amino acid concentrations are normal, so that the amino-aciduria must be due to faulty tubular reabsorption of amino acids.

In addition to amino acids, large amounts (50 to 200 mg. daily) of indican, indole-3-acetic acid and indole-3-acetyl-glutamine, derivatives of tryptophane, are present in the urine.

The parents of the family in which this disorder was first found were first cousins and were unaffected. Four of the eight siblings had the urinary findings of the disorder,

and two of these had the complete syndrome. The disease is apparently transmitted by an autosomal recessive gene. Several other instances of Hartnup disease have been detected in persons of English origin with disorders diagnosed initially as pellagra.

Large doses of nicotinamide cause a sustained remission of the disorder. However, amino-aciduria and urinary loss of indole compounds are not suppressed by such therapy.

#### **DISORDERS INVOLVING LEUCINE,**

##### **ISOLEUCINE AND VALINE (BRANCHED-CHAIN AMINO ACIDS)**

The essential branched-chain amino acids leucine, isoleucine and valine have conspicuous but as yet undetermined roles in two different hereditary metabolic diseases. In one disorder increased levels of all three amino acids are present in the blood and urine. In the second disturbance a deleterious effect of dietary protein has been identified specifically with leucine and one of its metabolites.

##### **INFANTILE IDIOPATHIC HYPOGLYCEMOSIS AND LEUCINE**

Marked lowering of the blood sugar level with convulsions has occurred in some patients with idiopathic hypoglycemia after the feeding of protein (p. 1218). A study of this phenomenon, produced by dietary casein but not by gelatin or tyrosine, in three members of one family and in another unrelated child showed that administration of leucine and its degradation product, iso-valeric acid, caused a fall in the true blood sugar level. The non-sugar-reducing substances of the blood, believed to be mainly glutathione and ergothioneine, also drop sharply after ingestion of leucine. Unlike the true blood sugar, the depressed levels of nonsugar-reducing substances do not rise when glucose is given. The mechanism and site of this action of leucine are unknown. However, demonstration of this etiologic factor in otherwise idiopathic hypoglycemia suggests the probability of other genetically determined causes for this metabolic disorder.

##### **MAPLE SUGAR URINE DISEASE**

This rare familial syndrome is a recently recognized molecular disease characterized by

the excretion of urine with an odor of maple sugar and evidences of cerebral damage appearing early in life. In the neonatal period there is difficulty in feeding, and the Moro reflex is absent. Progressive spasticity is followed by coma and early death.

The blood and urine of one recorded patient contained elevated levels of the three branched-chain amino acids, valine, leucine and isoleucine. The infant also had low blood

levels of threonine, serine, alanine and cystine and an increased concentration of methionine, but these were considered secondary changes. The nature of the primary defect is unknown, but a single enzymatic deficit could be the basis for involvement of all three acids, e.g., a lack of an aminopeptidase which normally incorporated these essential amino acids into protein. Valine deficiency in the rat causes severe neurologic disturbances.

## INBORN ERRORS IN CARBOHYDRATE METABOLISM

### *Defective Mucopolysaccharide Metabolism*

#### HURLER'S SYNDROME

The stored material, apparent as large vacuoles in the cells of many tissues of patients with the Hurler syndrome or gargoylism, has recently been identified as an acid mucopolysaccharide. The complex carbohydrates which are included in this chemical species are fundamental building units for connective

tissue. Two mucopolysaccharides isolated from the urine of patients with gargoylism are similar to the stored material in the cells. It is suggested that Hurler's syndrome is an inborn error of metabolism which is characterized by an overproduction of certain acid mucopolysaccharides, with abnormal storage in cells and with renal excretion of them.

### *Defective Glycogen Metabolism*

#### GLYCOGEN DISEASE

Glycogen disease is the generic term applied to a group of disorders of carbohydrate metabolism characterized by storage of abnormally large amounts of glycogen in various body tissues. The biochemical common denominator of the five clinically recognized types of glycogen disease is an inability of varying severity to break down glycogen. The complex structure of glycogen and the multiple enzymes involved in its degradation make it obvious that any one of several biochemical and enzymatic aberrations may be responsible for the abnormal stability of glycogen. In three of the clinical varieties of this disorder a deficiency of a single and different enzyme is associated with each type. The enzymatic deficit in the other two clinical variants is unknown. As yet there is no recorded instance of more than one type of disturbance in a single family tree.

#### HEPATORENAL GLYCOGEN STORAGE DISEASE

(VON GIERKE'S DISEASE, HEPATONEPHROMEGALIA)

The disorder is apparently transmitted on a recessive basis. The studies of the Coris have

clarified a number of the biochemical defects in the disorder. Glycogen is a polydisperse polysaccharide of high molecular weight (mean range, 3 to 6 million). It is composed entirely of glucose units linked together. The nature of these linkages is shown in Figure 62.

Although other tissues, such as skeletal muscle, utilize the Embden-Meyerhof carbohydrate glycolytic pathway (Fig. 63) for the production of energy by degrading their stored glycogen to lactic acid (glycogenolysis), the liver uses this metabolic pathway chiefly to synthesize glycogen and glucose from lactate and other precursors (glycogenesis and gluconeogenesis). The enzyme glucose-6-phosphatase, present in hepatic but not in muscle cells, enables the liver to supply the blood with free glucose from glucose-6-phosphate, a function which muscle is unable to perform.

Glucose-6-phosphatase activity is deficient in the hepatic and renal cells in patients with von Gierke's disease. Blocked metabolism in the glycolytic pathway at glucose-6-phosphate causes retrograde accumulation of glycogen. The inefficiency or failure in forming glucose from hepatic glycogen or from other precursors which enter the Embden-Meyerhof pathway results in instability of the blood

FIG. 62. The nature of the linkages of the glucose units in glycogen. The phosphorylase reaction forms or breaks the 1:4 linkages of glucose-1-phosphate molecules, which unite the units of glucose into chains. The linkage of chains at the branching points is between the 1:6 carbon atoms of adjacent glucose molecules. The branching enzyme forms this 1:6 union, and the debranching enzyme disrupts it.

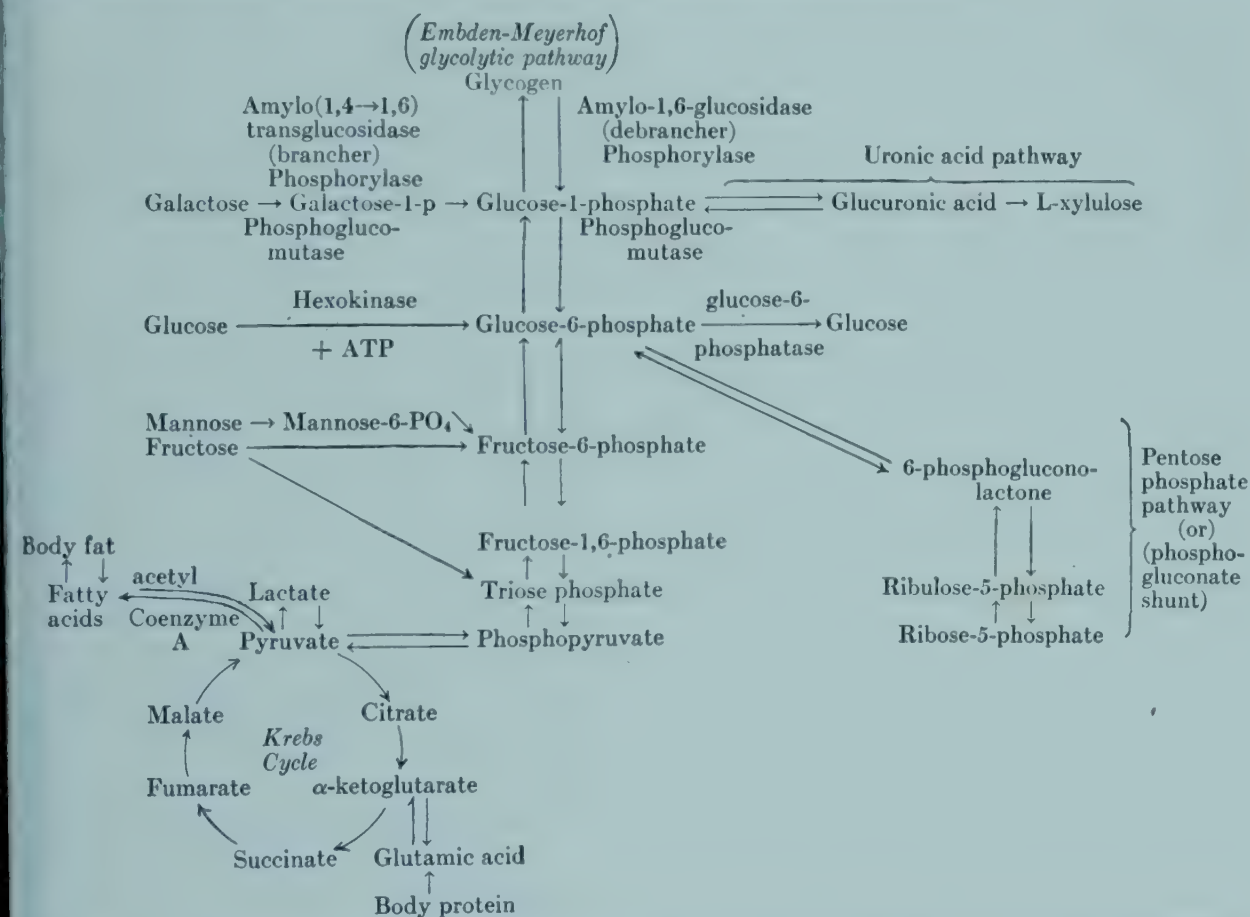

FIG. 63. Pathways of glucose metabolism in the cells, showing activation of inert glucose to glucose-6-PO<sub>4</sub> by hexokinase and ATP, and either storage as glycogen or glycolysis and degradation via the Embden-Meyerhof cycle and the Krebs cycle. Regeneration of glucose by the breakdown of glycogen (glycogenolysis) occurs only in the liver, since the enzyme glucose-6-phosphatase appears only there. Thus muscle can degrade glycogen to lactic acid, but it cannot liberate glucose.

The points at which the hexoses fructose, galactose and mannose enter the stream of glucose metabolism are indicated.

The reversibility of the metabolic pathway of glucose permits the formation of glucose and glycogen from tissue fat and protein by the utilization of fragments of glycerol, fatty acids and amino acids introduced into the Krebs tricarboxylic acid cycle. The oxidative processes in the Krebs cycle yield about 8 times more energy than the anaerobic glycolytic breakdown of glucose to lactate.

The phosphogluconate shunt is not only a pathway for the formation of pentose (ribose), but also is important in lipogenesis, in that 80 per cent of the carbohydrate metabolism of adipose tissue proceeds by this pathway.

sugar concentration and in hypoglycemia during periods of stress and fasting. The shift to fat metabolism is evidenced by hyperlipemia, fatty infiltration of the liver, ketosis and acetonuria. The accumulation of fat which gives many of the dwarfed children with this disorder a doll-like appearance is probably the result of conversion of unutilized glucose to fat. Impairment of protein synthesis is a likely cause of growth failure.

The enlarged smooth liver may contain 12 to 16 per cent of glycogen in contrast to an average normal content of 5 per cent (range, 3.2 to 7.6 per cent). The cytoplasm of the large hepatic cells, with small centrally placed nuclei, is filled with glycogen droplets, which would appear as empty spaces if the tissue had not been properly fixed after its removal. Intracellular fat is increased. Accumulation of glycogen in the renal convoluted tubules is responsible for the swollen kidneys. Slight increases are present in skeletal and cardiac muscle, and the smooth muscles may show moderate increases. White blood cells also contain glycogen globules. The presence of excess glycogen in the hepatic or renal cells is not conclusive evidence of the existence of von Gierke's disease; it must be demonstrated that spontaneous autolysis does not occur as an indirect proof of the enzymatic deficiency. In some instances fat deposition is so heavy that the excess of glycogen is obscured.

**Clinical Manifestations.** Variations in the severity of von Gierke's disease result in differences in the age at appearance of symptoms, in the intensity of the illness and in the prognosis. In the majority of patients the disorder has an insidious onset. Hepatomegaly is present at birth, but the abdominal enlargement may go unnoticed, since there are often no other symptoms during the first year of life. Gradually symptoms of hypoglycemia appear. Vomiting, more common at night, is frequent. Drowsiness, twitching and occasionally coma or convulsions may occur. Clinical manifestations of ketosis and acidosis are common complications of intercurrent infections. With advancing age the symptoms may become milder, and infrequently the hepatomegaly tends to regress in adulthood.

Occasionally, severe disturbances appear in the neonatal period, often within the first days of life, with tachypnea, dehydration and acidosis. Such infants are severely affected by the disorder and have fatty infiltration of the liver. Many die in early infancy.

Acetonuria is common and is increased during fasting. Ketonemia and elevated blood lactic acid levels lower the plasma carbon dioxide content. The fasting level of blood sugar is low, and the concentration is not increased by injection of epinephrine or glucagon in most patients. In mild cases of von Gierke's disease the hepatic glucose-6-phosphatase activity is only slightly depressed and there may be moderate elevation of the blood sugar after injection of epinephrine. The glucose tolerance curve is characterized by a high blood level after administration of glucose with a delayed return to normal range. Galactose tolerance is unimpaired. Hyperlipemia is common, especially early in the disease. The serum inorganic phosphate levels may be low, and elevation of the glycogen content of the blood has been observed. These laboratory findings are supportive but not diagnostic; demonstration of an increased amount of *stable* glycogen in hepatic or renal tissue constitutes proof.

**Treatment.** Though there is no corrective therapy for the biochemical defect in the liver, symptomatic measures can provide some relief by approximating physiologic levels of blood sugar. Protein aids in sustaining blood glucose levels and thus may prevent or minimize ketosis, acidosis, dehydration, hyperlipemia and perhaps the growth failure. Four or more meals, with protein constituting 25 per cent of the total calories, are advisable a day, the last being given at midnight. In one infant with severe early morning manifestations of hypoglycemia a formula containing 40 per cent protein given in three bottle feedings a day produced complete symptomatic relief. Corticosteroids may be helpful in controlling hypoglycemia during critical periods.

Prolonged withholding of food for diagnostic procedures should be avoided. The ease with which acidosis and hypoglycemia develop in the course of an infection should be anticipated and prevented by provision of adequate amounts of fluid containing glucose and sodium lactate or bicarbonate.

#### **DIFFUSE GLYCOGENOSIS WITH HEPATIC CIRRHOSIS**

(FAMILIAL CIRRHOSIS OF THE LIVER WITH STORAGE OF ABNORMAL GLYCOGEN)

This variety of hepatic glycogen disease, in which there is cirrhosis, splenomegaly, ascites and widespread accumulation of a chemi-

cally abnormal glycogen in various tissues, was identified by Anderson from autopsy findings in two siblings. The same disorder was apparently present in a number of cases previously reported as familial cirrhosis or hepatic glycogen disease with cirrhosis. Unlike von Gierke's disease, the fasting blood sugar and the glucose tolerance curve in the single patient studied were normal. The response to epinephrine, however, was poor, and hypoglycemic crises, acidosis and ketosis were absent. Impaired hepatic functions were manifest by abnormal thymol turbidity and cephalin flocculation tests, by low serum albumin and elevated serum globulin levels, by brom-sulfalein retention and by increased serum bilirubin concentration. All known patients have died at ages ranging from seven months to ten years. Treatment is entirely symptomatic.

Large amounts of glycogen were present in the diffusely nodular cirrhotic liver, smaller amounts in the spleen and none in the kidneys. The reticuloendothelial cells contained excessive glycogen and reacted to it as if it were a foreign material. Chemical studies of the glycogen by Cori revealed an abnormal molecule resembling that of amylopectin of maize starch. On the basis of these observations a hepatic deficiency of the enzyme amylo (1:4  $\rightarrow$  1:6) transglucosidase has been postulated. It is suggested that the hepatic and splenic fibrosis is a foreign body reaction to the abnormal starchlike glycogen.

#### GLYCOGEN STORAGE DISEASE OF LIVER AND MUSCLE

##### (LIMIT DEXTRINOSIS)

There are nine recorded cases of this rare familial disorder, which is characterized by large accumulations of chemically abnormal glycogen in the liver and voluntary muscles, with lesser amounts in the heart, and with little if any in the kidneys. The clinical and anatomic findings resemble those of mild cases of von Gierke's disease. Aside from abdominal enlargement due to hepatomegaly, which appears in infancy, and a craving for sweets, these patients appear well and may grow in fairly normal fashion. Fasting blood sugar levels are low and respond with slight rises to injection of epinephrine. Acetonuria occurs with fasting. The oral glucose tolerance curve rises to a high level and falls slowly. In later childhood there may be such evidences of portal hypertension and disturbed liver function as prominent abdominal veins, hy-

percholesterolemia and retention of brom-sulfalein. Sections of the liver reveal excessive deposition of glycogen and mild cirrhosis.

Cori has demonstrated an abnormal glycogen, a deficit or complete absence of the hepatic debrancher enzyme amylo-1:6-glucosidase, and suggested the name *limit dextrinosis* for this disorder.

Although two patients have died in infancy, one apparently normal woman of thirty-two years of age has been observed.

#### CARDIAC GLYCOGEN DISEASE

Cardiac glycogen disease is a rare familial condition which differs not only clinically, but also pathologically and chemically, from the hepatic type. About twenty-five cases are recorded. Though the heart is the most prominent site of glycogen accumulation, there is equally striking deposition in the voluntary muscles. Massive glycogen deposition in the cardiac muscle produces a "lacework" appearance of the fibers in microscopic sections and is responsible for the enlargement of the heart to as much as five times its normal size. Accumulated vacuoles of glycogen increase the diameters of voluntary muscle fibers from two to five times. The degree of vacuolization varies from muscle to muscle, but is always great in the tongue. Smooth muscle cells and reticuloendothelial cells show considerable glycogen infiltration. Smaller amounts are found in almost all other organs and tissues, including the central nervous system (p. 1095).

The glycogen of the cardiac variety, in contradistinction to that of the hepatic type, is unstable post mortem and undergoes autolysis at rates which are usually within normal limits. Chemical analysis has failed to uncover an enzymatic defect or any abnormality of the glycogen. There are no detectable derangements of carbohydrate metabolism, and the elevated serum lipid and cholesterol levels seen in von Gierke's disease are not encountered.

Symptoms related to impaired cardiac function may be manifest at birth and in most instances become evident within the neonatal period. Cyanosis, dyspnea, tachypnea and restlessness are common. With advancing cardiac embarrassment, anorexia, listlessness and cough may appear. The heavy glycogen infiltration of other tissues may produce clinical manifestations which are confusing. Mistaken diagnoses of mongolism, cretinism and amyotonia congenita have been

made on the basis of thickening of the tongue and extreme muscular hypotonicity. Neurologic abnormalities may be prominent when there is massive infiltration of the central nervous system with glycogen (p. 1095). The heart is greatly enlarged and has a circular appearance in roentgenograms. Murmurs are usually absent. Electrocardiographic tracings may show such changes as pronounced left axis deviation, inverted T waves and widened QRS complexes. Death usually occurs between one and eight months of age.

Though this disorder is rarely diagnosed before death, it should be considered a possibility in all infants under eight months of age with cardiac enlargement and failure not otherwise readily explained. Demonstration of increased glycogen content in muscle tissue supports the diagnosis, but does not confirm it, since other conditions may cause similar deposition. Aberrant origin of a coronary artery from the pulmonary artery, transposition of the great vessels, cor pulmonale in cystic fibrosis of the pancreas, acute inter-

stitial myocarditis and endocardial sclerosis, in particular, must be considered in the differential diagnosis.

Other than symptomatic therapy, no treatment is available.

GLYCOGEN DISEASE OF SKELETAL MUSCLE

(NEUROMUSCULAR GLYCOGEN DISEASE)

This rare familial disorder, of which there are ten recorded cases, is characterized by clinical manifestations resembling Werdnig-Hoffmann syndrome (p. 1100) and excessive storage of glycogen in the striated muscles. It is apparently transmitted by a recessive gene. Progressive muscular weakness, present at birth or appearing in the early months of infancy, is the most conspicuous finding. Intention tremor and spasticity may appear initially. Bulbar symptoms, especially dysphagia necessitating tube feeding, are prominent. The muscles are often enlarged, resembling those of pseudohypertrophic muscular dystrophy. About half of the patients

Table 48. Characteristics of the Various Glycogen Disorders

Type of Glycogen Disease	Relative Incidence	Organs Most Conspicuously Involved	Age		Clinical Findings				Enzymatic Defect
			At Onset of Recognition	At Death	Characteristic Appearance	Hypoglycemia, Hyperlipemia, Ketosis	Blood Sugar Elevation after Epinephrine	Structure of Glycogen	
Von Gierke's hepatorenal glycogen disease	Commonest variety; more than 100 recorded cases	Liver, kidney	Neonatal period (severe) to 2 years (mild)	Varies with severity; may live to adulthood	Dwarfism with hepatomegaly	++++	0 to ++	Normal	Glucose-6-phosphatase; degree of deficiency varies
Glycogen disease of liver (cirrhosis) and reticuloendothelial system	Very rare; one recorded family	Liver, including cirrhosis, reticuloendothelial system	Late infancy	Infancy to prepubertal period	Resembles von Gierke's disease with findings of severe hepatic cirrhosis	0	++	Long outer chains like amyloextrin (starch); fewer branch points	Brancher enzyme (amylol-1:4→1:6 transglucosidase)
Glycogen disease of liver and muscles with mild cirrhosis (limit dextrinosis)	Rare; 6 reported cases	Liver, including mild cirrhosis; skeletal muscles; cardiac	Late infancy	Varies with severity; may live to adulthood	Resembles von Gierke's disease with findings of mild hepatic cirrhosis	++	+	Short outer chains; numerous branch points	Debrancher enzyme (amylol-1:6 glucosidase)
Glycogen disease of the heart with generalized glycogenosis	Second most common; about 20 reported cases	Cardiac muscle; skeletal muscles (tongue); smooth muscle; reticuloendothelial system	Neonatal period	Usually within first year	Cardiac findings; may have mongoloid expression	0	Normal	Normal; muscle cells contain vacuoles of acid mucopolysaccharide	Unknown
Glycogen disease of the skeletal muscles with cardiomegaly and C.N.S. changes	Rare; 8 recorded cases	Skeletal muscle; central nervous system, heart, and others	Neonatal or early infancy	From 5 to 46 months; most under 1 year	Resembles amyotonia congenita; bulbar signs	0	Normal	Abnormal in 1 case; (short outer chains), vacuoles in muscle cells containing acid mucopolysaccharide	Unknown; presumably 1 case of debrancher enzyme

have macroglossia and are easily confused with cretins. Occasionally the facies may have a mongolian appearance. There is cardiac enlargement of moderate degree, but cardiac symptoms are usually absent. Hepatomegaly without splenic enlargement is common.

There are no characteristic abnormal chemical changes in the urine and blood, and the mechanisms for maintenance of physiologic blood sugar levels are intact.

The massive glycogen deposition in the muscle fibers and the presence of numerous vacuoles containing large amounts of acid mucopolysaccharide resemble the changes in the myocardial fibers in cardiac glycogen disease. There is also excessive glycogen in cardiac muscle and in hepatic cells, and considerable accumulations in nervous tissue in

about one third of the cases. Generalized glycogenesis involving all tissues studied has also been observed. Studies by Zellweger suggest a deficiency of the debrancher enzyme. Overlapping clinical and laboratory findings of the muscle and cardiac glycogen diseases suggest that they may be variants of a single genetic defect. However, the clinical pattern of progressive muscular weakness, bulbar symptoms, absence of cardiac symptoms and the high incidence of glycogen accumulation and degenerative changes in nervous tissue delineates glycogen disease of skeletal muscle as a clinical entity.

Most patients with this disorder die in infancy, usually during the first year; the longest known survival period has been forty-six months.

## *Defective Disaccharide Metabolism*

### **SUCROSURIA**

(SACCHAROSURIA)

This rare hereditary defect is a failure of hydrolysis of sucrose in the intestinal tract, so that it is absorbed intact and excreted in the urine. In one infant the urinary excretion of sucrose was increased by ingested fructose

or sucrose, suggesting an anomalous enzymatic synthesis of cane sugar in the body from fructose and glucose. Cane sugar does not reduce copper solutions. Patients with sucrosuria may have symptoms resembling those of diabetes, such as polyuria, polydipsia and loss of weight, without a reducing substance in the urine.

## *Defective Hexose Metabolism*

### **ESSENTIAL FRUCTOSURIA**

(LEVULOSURIA)

This rare and benign congenital abnormality of carbohydrate metabolism is characterized by the presence of fructose (levulose) in the urine. It results from an inability to metabolize fructose, so that it accumulates in the blood. The resultant high concentration of fructose in the glomerular filtrate exceeds the normally low tubular reabsorptive capacity for this sugar, and it is lost in the urine. Fructose occurs as a monosaccharide in many fruits and vegetables and in honey. It is also derived from the intestinal hydrolysis of sucrose and of the complex polysaccharides in onions, garlic, sugar beets and Jerusalem artichokes.

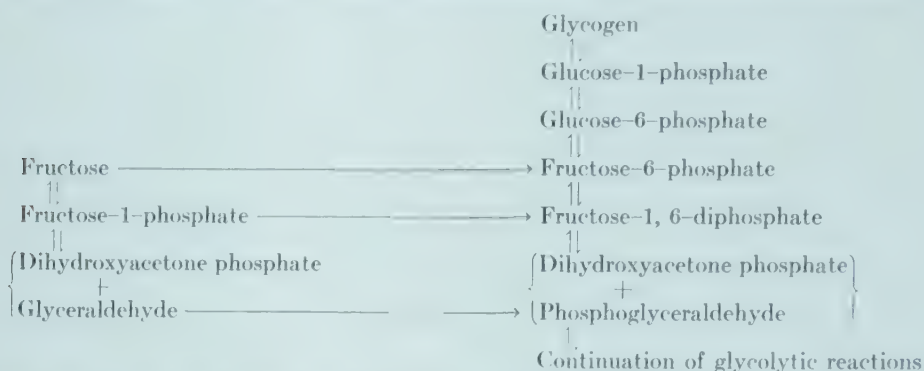

From 10 to 20 per cent of ingested fructose is excreted in the urine of patients with the defect. Inherited as a recessive trait, essential fructosuria occurs in less than one in

100,000 persons; all known patients have been white. The lifelong urinary loss of ingested fructose is without serious consequence.

Fructose reduces Benedict's or Fehling's solutions and is fermented by yeast. It may be differentiated from glucose by polariscopic examination; it has a specific optical rotation of  $-90^\circ$  (levorotatory) compared to glucose, which is  $+52^\circ$  (dextrorotatory). It also forms characteristic crystals of methylphenylhydrazine and osazone.

Other causes of fructosuria must be eliminated before it can be designated as essential. In acquired hepatic disorders such as infectious hepatitis, cirrhosis and syphilitic hepatitis, fructose is occasionally found in the urine if the hepatocellular damage is severe. As an extreme rarity, fructosuria has been encountered in association with severe diabetes mellitus. In an alkaline urine, glucose may be converted to fructose.

The metabolism of fructose in normal tissues proceeds according to the following scheme:

Fructose enters the major glycolytic pathway by three channels. Phosphorylated to fructose-6-phosphate, it is introduced directly into the main stream of carbohydrate metabolism. After conversion to fructose-1-phosphate it joins the glycolytic pathway by additional phosphorylation to fructose-1, 6-phosphate and by splitting into two fragments. One of these, glyceraldehyde, joins the glycolytic pathway as phosphoglyceraldehyde. From this point glucose and fructose follow the same metabolic pathways in both directions of the chain of glycolytic reactions.

Since the loss of dietary fructose in the urine is apparently harmless, no treatment or dietary restriction is indicated.

### HEREDITARY FRUCTOSE INTOLERANCE WITH HYPOGLYCEMIA

An inborn error of fructose metabolism with serious clinical disturbances has been observed in four members of a single family, two children and two adults in different generations. Hypoglycemia with severe symptoms occurred after ingestion of fructose. Administration of an oral test dose of this sugar (20 to 50 gm. per square meter of body surface) to an affected person was followed by a steep and prolonged rise in the blood level of fructose, with a simultaneous fall in the blood level of glucose to 10 mg. per 100 ml. The severe hypoglycemia persisted for several hours and was accompanied by nausea, vomiting, sweating, tremor and drowsiness. After the cessation of acute symptoms slight transient icterus was noted.

The disorder appears to be transmitted by an autosomal recessive gene.

### GALACTOSEMIA

Galactosemia, a congenital error in the metabolism of galactose, is responsible for retardation of growth and development and widespread tissue injury. It is inherited as a recessive trait, and is not as rare as the small number of recorded patients would indicate.

The severity of the tissue changes associated with galactosemia is directly propor-

tionate to the quantity and duration of galactose ingestion. Galactose does not occur in free form in foods; intestinal hydrolysis of the lactose of milk and milk products yields glucose and galactose. Less important food sources are the glycogen-like compound galactogen in snails and the polysaccharide raffinose in sugar beets, which yields glucose, fructose and galactose. Galactose cannot be utilized directly by cells as a source of energy, but must first be converted to a glucose compound. The transformation of galactose to glucose occurs chiefly in the liver. However, most, if not all, normal tissues, including the erythrocytes, can effect this conversion to some extent. Deficiency of the enzyme phosphogalactose uridyl transferase, which catalyzes the first of the three metabolic steps, is the inborn error in galactosemia (Fig. 64). The resultant metabolic block leads to an accumulation of galactose-1-phosphate in the tissue cells. The enzymatic deficit persists throughout life in hereditary galactosemia; temporary galactose intolerance occurs normally and in various disease states.

Galactose, unlike glucose, is not fermented by yeast. By determining the blood sugar before and after yeast fermentation the amounts which each of the sugars contributes to the total blood sugar can be separated. Identification of the nonfermentable sugar as galactose may be established by the phenylhydrazine test, which yields typical galactosazone crystals. The mucin test with nitric acid results in crystals characteristic of either galactose or lactose. Lactose may be ruled out by a yellow reaction with the Rubner test. Galactose

is also readily determined by paper chromatography. By individually determining blood glucose and galactose levels, Hartmann has shown that as much as 40 per cent of the blood sugar in normal infants on a milk diet may be galactose. This limited capacity for converting galactose to glucose in normal infants is greatly exaggerated in infants recovering from severe diarrhea when fed milk after a period of nonmilk feeding or starvation. Such infants frequently have high blood galactose levels, with those of glucose depressed to hypoglycemic levels. The abnormal galactose tolerance tests in patients with liver disease or hyperthyroidism indicate similar depression of the hepatic enzymatic conversion mechanism. When the blood galactose is elevated to a level which exceeds the capacity of the renal tubules to reabsorb it from the glomerular filtrate, galactose appears in the urine.

The clinical findings in galactosemia are apparently due to the deleterious effect of galactose-1-phosphate on cellular metabolism. The observation that enzyme deficient galactosemic erythrocytes have impaired oxygen utilization, while normal red cells are unaffected when exposed to galactose, indicates that a metabolite of galactose rather than the sugar itself is the injurious agent.

Proteinuria, amino-aciduria and occasionally hyperchloremic acidosis are evidences of renal cellular injury expressed as glomerular

and tubular dysfunctions. These are reversible phenomena, appearing some days after galactosuria begins, and disappearing slowly when lactose is excluded from the diet. Demonstrable pathologic changes predominate in the liver, beginning as fatty infiltration and progressing to cirrhosis. The brain and kidneys show minor and nonspecific changes.

Infants with galactosemia appear normal at birth. Galactosuria is present as soon as milk or lactose water is fed. The severe form of the disease may begin during the first or second week. Listlessness, feeding difficulties, vomiting and weight loss may be the first manifestations. Subclinical early hepatic damage may be responsible for jaundice, which may seem to be a continuation of the neonatal physiologic jaundice. Hepatomegaly and splenomegaly are evident quickly as early signs of portal obstruction, and nuclear cataracts appear about the same time. Galactosuria fluctuates in a degree with the lactose intake and is more severe in breast-fed infants because of the high lactose content of breast milk. Protein, casts and amino acids are present in the urine as signs of renal damage. With the onset of hepatic failure, hemorrhages, due to prothrombin deficiency, occur in the skin and mucous membranes, and generalized edema and ascites develop. At this stage the infant is usually emaciated, lethargic and hypotonic; death may occur from infection or severe hepatic failure.

FIG. 64. Pathways of lactose and galactose metabolism.

In some infants the manifestations of galactosemia evolve more slowly and are milder. The discovery of hepatomegaly and cataracts in an underweight, but not acutely ill, three- or four-month-old infant may be the first indication. A significant degree of mental retardation occurs in most infants, and cirrhosis of the liver, cataracts and mental deficiency may remain as permanent sequels.

Examination of the relatives of galactosemic infants, with the galactose tolerance test, reveals a number with galactose intolerance as the only evidence of a subclinical form of galactosemia. Such persons often have a history of gastrointestinal milk intolerance during infancy, and some have a lifelong aversion to milk. The recent discovery of an alternate metabolic pathway for galactose may explain the variations in the clinical severity of galactosemia and account for the acquisition of tolerance for galactose with advancing age. The capacity for expansion of this minor enzymatic pathway (Fig. 64) should determine the amount of galactose-1-phosphate which bypasses the primary metabolic block and re-enters the pathway to glucose formation.

The sudden depression of glucose concentration which follows the rapid influx of galactose into the blood during the performance of a galactose tolerance test may produce clinical manifestations of hypoglycemia. For this reason the test should be used only when it is difficult to diagnose galactosemia by other means.

Amino-aciduria is a feature of the severe form of galactosemia. More than twenty different amino acids have been identified, the pattern of excretion varying from patient to patient. Proteinuria is present in all untreated infants and may amount to 1 gm. daily.

Hyperchloremic acidosis due to renal tubular dysfunction and hypokalemia are not uncommon. Increased plasma levels of bilirubin and alkaline phosphatase, prolonged prothrombin times and positive cephalin flocculation tests may be found early in the clinical course. The specific enzyme deficiency in patients with this disorder can be easily demonstrated in the erythrocytes by a relatively simple spectrophotometric test with umbilical cord blood.

Withdrawal of milk from the diet and substitution of a lactose-free diet result in cessation of galactosemia and galactosuria and, early in the clinical course, in disappearance of the abnormal clinical findings. Cataracts which persist require surgical treatment. The small quantities of galactose (less than 0.1 per cent) present in milk substitutes made with casein hydrolysates may be toxic to the tissue cells of affected infants even though they do not raise the blood galactose level high enough to cause galactosuria. Similarly, soy bean preparations are unsatisfactory substitutes because they contain stachyose, a complex polysaccharide composed of two molecules of galactose and one each of fructose and glucose. Holzel has successfully used a feeding mixture composed of cereal, egg and vegetable margarine as a galactose-free substitute for milk.\* Strict avoidance of milk, milk products and such unsuspected sources as lactose-containing tablets for the first three years of life is recommended as the best guarantee for normal growth of the brain.

Dietary lapse should be suspected as a cause of an illness in a treated infant, especially if hepatomegaly or jaundice develops. In the absence of galactosuria, amino-aciduria is a sensitive indicator of the presence of galactose in the diet.

### *Defective Pentose Metabolism*

More slowly absorbed than hexoses, the pentoses enter the main glycolytic pathway of carbohydrate metabolism by a collateral chan-

\* Holzel's formula is an adaptation of a milk-free pudding devised by Moll and Stransky.

*The ingredients:* 2 eggs, 6 ounces of cereal (containing no milk powder), pinch of salt, pinch of bicarbonate of soda and oleomargarine (without added butter).

*Method of preparation:* The egg yolks and sugar are beaten together. The egg whites, to which the pinch of salt and sodium bicarbonate are added, are beaten until stiff. The cereal is mixed thoroughly

nel, the pentose phosphate pathway (Fig. 65). Pentoses such as D-ribose and desoxyribose which are part of the molecular structure with water. All ingredients are mixed and cooked in a double boiler for 20 to 30 minutes. The cooking pan is greased first with oleomargarine and dusted with dry cereal. The amount of oleomargarine is gradually increased to 1 ounce at 3 to 4 months of age.

One part of this pudding is added to 4 parts of boiled water or weak tea, mixed well and strained before being put into the nursing bottle.

Additional calcium must be given daily.

FIG. 65. Metabolic pathways for pentose. Two pentose-hexose cycles by which the metabolism of pentoses is integrated with the major pathway of glucose metabolism, the glycolytic pathway.

A, The pentose phosphate pathway is the metabolic sequence of reactions in which phosphate is used for energy. D-ribose is synthesized and incorporated into the various nucleosides, which in turn become part of the ribose nucleic acids (RNA) which characterize the nucleoproteins.

B, The glucuronate-xylulose pathway establishes the long obscure link between L-xylulose and the metabolism of glucose. The compound D-xylulose-5P is unique, in that it is a focal point in carbohydrate metabolism similar to glucose-6P. It links the 2 pentose pathways, and from it branches a pathway over which L-arabinose is metabolized.

ture of nucleoproteins are not derived directly from dietary sources; they are synthesized as needed from glucose by a sequence of metabolic reactions via the pentose phosphate pathway. Renal tubular reabsorption of filtered pentose is poor, so that a considerable portion of the pentose absorbed from the bowel may be lost in the urine. In such instances the urinary pentose is either xylose or arabinose. The presence of D-ribose has been noted in the urine of some patients with muscular dystrophy.

## ESSENTIAL PENTOSURIA

### (L-XYLULOSURIA)

This is a rare inherited anomaly characterized by excretion of L-xylulose regardless of diet. Found almost exclusively in Jewish families, it has an incidence of about one in 50,000. Most cases are not detected until adult life;

however, it has been encountered in a nineteen-month-old infant. The disorder is transmitted by an autosomal recessive gene.

Until recently the origin of the metabolic defect responsible for the presence of L-xylulose in pentosuria was unknown. It was recognized that feeding of D-glucuronic acid or of compounds which appear as D-glucuronides, such as menthol, borneol, amidopyrine and codeine, caused increased amounts of L-xylulose to appear in the urine of pentosurics. With the complete delineation of a second pentose-hexose cycle, in which many of the metabolic intermediate compounds are not phosphorylated, it is now clear that the precursor of L-xylulose, D-glucuronic acid, is derived from glucose. This metabolic chain connecting L-xylulose to the main stream of carbohydrate metabolism, the Embden-Meyerhof glycolysis schema, is called the glucuronate-xylulose pathway of pentose metabolism

(Fig. 65). A metabolic block beyond L-xylulose, preventing its re-entry into the pentose phosphate pathway, is one possible explanation for L-xylulosemia.

L-xylulosemia is usually harmless and symptomless; in some families an association with migraine has been noted. It is ordinarily

discovered by urinalysis; because it reduces Benedict's and Fehling's solutions it may be confused with glycosuria. L-xylulose is not fermented by yeast. With phenylhydrazine it forms an osazone which melts at 158° C. The reaction of orcin with Bial's reagent\* is positive.

## INBORN ERRORS OF LIPID METABOLISM

### IDIOPATHIC HYPERLIPEMIA

#### (FAMILIAL HYPERLIPEMIA)

Idiopathic hyperlipemia is a comparatively rare disorder of fat metabolism characterized by an increase in the neutral fat fraction of the blood. Of twenty-four reported cases, eleven were children and twenty-two were males. Both the white and Negro races are affected. The familial occurrence of hyperlipemia makes it likely that it is an inborn error of metabolism transmitted as a recessive trait.

The *pathogenesis* of idiopathic hyperlipemia is obscure. An unesterified fatty acid fraction, which is bound to protein, is the active transport form of blood fat. It is released from adipose tissue by the enzyme lipoprotein lipase. Whether this mechanism is disturbed in idiopathic hyperlipemia is unknown. The demonstrable pathologic changes, hepatosplenomegaly, lipemia retinalis, xanthomatous skin lesions and fat storage cells in sternal marrow result from storage of fat in the reticuloendothelial cells secondary to the excess blood lipids.

Clinically, the following triad of *symptoms* should suggest idiopathic hyperlipemia: (1) abdominal pain, usually recurrent and colicky and possibly related to meals. In the patient observed by Holt, such abdominal crises suggestive of a surgical condition took place when the blood fat rose to 8 per cent. Nausea and vomiting are not uncommon. (2) Hepatosplenomegaly, presumably due to deposition of fat; (3) xanthomatous skin lesions consisting of yellowish papules with an inflammatory halo.

In more than half of the patients lipemia retinalis was observed funduscopically. A level of blood fat of more than 3.5 per cent

gives the peripheral retinal vessels a pink appearance, so that it is difficult to distinguish veins and arteries. The parents and siblings of some reported cases had lesser degrees of hyperlipemia and were asymptomatic.

The excess neutral fat in the plasma produces a grossly chylous or milky white appearance. The other blood lipids, cholesterol, cholesterol esters and the phospholipids (sphingomyelin, cephalin and lecithin), are constantly but less markedly increased; they do not contribute to the chylous appearance of the serum. Hyperlipemia occurs physiologically after a meal of high fat content, reaching its peak in three hours. It is also seen in a variety of pathologic states, such as the nephrotic syndrome, renal vein thrombosis, poisoning with phosphorus, chloroform and carbon tetrachloride, starvation, anoxia, anemia, hypoproteinemia, leukemia, diabetes, hepatic glycogen disease, Niemann-Pick disease, hypothyroidism and pancreatic disease. There should be no difficulty in differentiating these disturbances from idiopathic hyperlipemia.

The clinical course of the disorder is relatively benign; thirteen of the reported patients were adults. However, sudden otherwise unexplained death has occurred.

There is no known cure. Low fat diets cause some decrease in blood fat, but not to normal levels. On such diets regression of many of the symptoms may occur.

\* *Bial's Reagent*: Dissolve 1 gm. of orcin in 50 ml. of hydrochloric acid (specific gravity, 1.51). Add 25 drops of 10 per cent aqueous ferric chloride. Keep in a dark bottle away from light.

*Orcin Test*: Overlay 5 ml. of Bial's reagent in a test tube with 5 drops of urine. A green ring appears at the junction of the 2 layers if xylulose is present.

## INBORN ERRORS OF PIGMENT METABOLISM

## THE PORPHYRIAS

The porphyrias are a group of hereditary metabolic errors involving the porphyrins, a class of pigments widely distributed in nature and occurring in plant and animal tissues. The porphyrins are derivatives of a parent substance, porphin, which consists of four pyrrole nuclei joined in an aromatic structure. Fischer showed that there were artificial isomeric porphyrins with methyl ( $\text{CH}_3$ ) and ethyl ( $\text{C}_2\text{H}_5$ ) groups in equal numbers as side chains. These he named the etioporphyrins I, II, III and IV. All the porphyrins occurring in nature are derivatives of either etioporphyrin I or III. Porphyrins of type I cannot be derived from type III. Thus the simultaneous occurrence of porphyrins of types I and III is interpreted as an independent synthesis of each type and is referred to as the "dualism" of the porphyrins. The respiratory pigments, hemoglobin, myoglobin, cytochrome, catalase, peroxidase and chlorophyll, are porphyrin derivatives. Free porphyrins occur in young cells of the erythrocyte series in the bone marrow.

Though porphyrins exist preformed in many food substances, including milk, bread, beer, fish, spinach, potatoes, rutabagas and green leaves, the porphyrins of the body are synthesized from simpler pyrroles. Porphyrins of types I and III are formed simultaneously in the body as products of the same chemical process from pyrrole precursors. Thus in the synthesis of hemoglobin and the other respiratory enzymes which contain protoporphyrin III in their molecules, one part of protoporphyrin I is formed as a by-product in the formation of 10,000 parts of the type III compound. The type III porphyrin combines with iron or specific protein to form the respiratory pigments, and the small amount of by-product coproporphyrin I is excreted.

In normal human adults (quantitative studies of porphyrin excretion in normal infants and children are lacking) from 14 to 100 micrograms of coproporphyrins are excreted in the urine daily. Approximately 80 per cent is the type I isomer (coproporphyrin I) and 20 per cent, type III (coproporphyrin III). In various pathologic conditions there is often a considerable alteration in the amount and ratio of the two types of porphyrin in the

urine. In certain hepatic diseases (obstructive jaundice, hepatitis with jaundice and cirrhosis) there is an increase in urinary coproporphyrin, usually of coproporphyrin I. In the febrile states associated with lung abscess and pneumonia and at times in rheumatic fever, increases in urinary coproporphyrin I also occur. In most cases of acute poliomyelitis there is an increased excretion of coproporphyrin III, which may be found in metallic and drug poisonings (lead, arsenic, sulfanilamide, chloral hydrate, Avertin, paraldehyde, ether, morphine, aspirin, phenacetin and acetanilid) and in various blood disorders (leukemia, aplastic anemia, pernicious anemia, hemolytic anemia and Hodgkin's disease).

In all the pathologic states mentioned the excretion of abnormally large amounts of porphyrin in the urine is referred to as *porphyria*, a term which must be distinguished from *porphyria*, which is the name applied to the congenital errors of metabolism of pyrrole pigments, in which there is also excretion of large amounts of porphyrins. It is convenient to divide the hereditary porphyrias into three clinical types, i.e., congenital porphyria, acute intermittent porphyria (hereditary) and the cutanea tarda type.

## "CONGENITAL" PORPHYRIA

## (ERYTHROPOIETIC PORPHYRIA)

Congenital porphyria is a rare metabolic error inherited as a recessive character. It may be present at birth and has been described in the fetus. The classic clinical manifestations of this disorder are excretion of a Burgundy red urine, discoloration of the bones and teeth, extreme sensitivity of the skin to light, and hirsutism. Hepatic and splenic enlargement is common. Not all these symptoms may be evidenced at one time or in one patient.

The biochemical defect in congenital porphyria may be a failure of conversion of uroporphyrin I, which is formed in excessive amounts, to coproporphyrin I. It is assumed that uroporphyrin is formed in postnatal life, but is ordinarily converted by decarboxylation of four  $-\text{COOH}$  groups to coproporphyrin I. The red color of the urine in congenital porphyria, which is due to the presence of excessive amounts of uroporphyrin I

FIG. 66. Porphyria showing (1) discoloration of the teeth; (2) pigmented scars of hydroa vacciniforme prominent on the forehead; and (3) hypertrichosis, manifested by the thick eyebrows joining in the midline, the long eyelashes and the low frontal hair line. (Dunskey, Freeman and Gibson: Am. J. Dis. Child., Vol. 74.)

and coproporphyrin I, has been noted at birth. In alkaline solutions porphyrins are reddish-brown; in mineral acid solutions they are purple or reddish-violet, and in organic acid solutions, a dull red. In many instances light-colored urine is passed which darkens after exposure to light, owing to photo-oxidation of leuco-porphyrins. In some patients with porphyria the urine becomes darker when the patient is exposed to sunlight. Once red urine is excreted, the passage of colored urine usually persists year after year. Conditions other than porphyrinuria may cause a reddish urine, so that hemoglobinuria, myoglobinuria and hematuria must be differentiated. The ingestion of beets or pyramidon may also color the urine red. A pink color is often seen in alkaline urines after ingestion of phenolphthalein, senna, cascara, rhubarb or santonin. In newborn and young infants precipitated amorphous urates frequently have a pink tinge. In congenital porphyria the passage of red urine usually precedes the appearance of cutaneous light sensitivity.

The presence of porphyrins in the tissues is responsible for the cutaneous sensitivity to sunlight. Like many other fluorescent com-

pounds, the porphyrins are sensitized by light and become powerful proteolytic agents. The porphyrins vary in their ability to sensitize tissues to light, the type I porphyrins, especially uroporphyrin I, being the most photodynamic. After exposure to sunlight the unprotected skin surfaces develop *hydroa aestivale*, a symptom complex which begins with itching and erythema and is followed by a vesiculobullous eruption that forms crusts and leaves pigmented scars. The tissue scarring is disfiguring and, when deep, may involve cartilage, ligaments and bones, resulting in mutilation or loss of parts of the nose, ears or fingers. Severe involvement of the conjunctiva and cornea may cause blindness. In some patients pigmentation and hirsutism develop in the skin surfaces exposed to sunlight. There are many cases of hydroa aestivale or vacciniforme not associated with congenital porphyria. *Hydroa is a symptom complex, but congenital porphyria with similar cutaneous lesions is a clinical entity due to a disorder of porphyrin metabolism.*

Continuous deposition of uroporphyrin I is responsible for the pigmentation of bones and teeth. Dark brown stained bones are in sharp contrast to the unstained cartilage. In about 10 per cent of patients the temporary and permanent teeth have a pink or purplish-brown discoloration (*erythrodontia*). Occasionally the fingernails are reddish-purple and may be shed during the summer after an episode of hydroa.

Splenomegaly due to increased hemolysis of erythrocytes is a regular occurrence, and the resultant increased bone marrow activity stimulates excessive formation and excretion of porphyrins. Clinical and chemical improvement may follow splenectomy.

Patients should be protected from sunlight with suitable clothing combined with application of "sun-tan" ointments or lotions capable of filtering out ultraviolet rays.

#### ACUTE INTERMITTENT PORPHYRIA (HEREDITARY)

Acute porphyria is a hereditary disorder of porphyrin metabolism in which there is urinary excretion of excessive quantities of type III porphyrin isomers. It is inherited as a dominant characteristic. Though a few children have had acute porphyria, it is usually manifest clinically between thirty and fifty years of age and is more common than congenital porphyria. There are no known cases of congenital porphyria in families with acute

porphyria. The precipitating factor of an attack is usually unknown, but attacks may be induced by ingestion of barbiturates and related compounds such as Sulfonal, Trional and Sedormid.

Patients with acute porphyria do not have unusual sensitivity to light or discoloration of the bones and teeth, but jaundice and a peculiar brownish pigmentation of the skin have been observed. Though there is great variation in the clinical picture, the symptoms are of three general types and appear intermittently and acutely: (1) abdominal symptoms, consisting in severe colicky pain, constipation and vomiting, often accompanied by fever, hypertension and tachycardia; (2) nervous symptoms, characterized by a symmetric progressive paralysis, at times accompanied by polyneuritis; and (3) psychotic disorders.

During an attack the urine is usually red, but in some instances it is yellow when excreted, becoming dark after exposure to light. In addition to the type III uroporphyrin, smaller amounts of uroporphyrin I and coproporphyrin I have been isolated from the urine of patients with acute porphyria. Various chromogens, responsible for some of the dark color, such as porphobilinogen and porphobilin, are also present in the urine. The porphyrin can be demonstrated in the urine by pink fluorescence in ultraviolet light, especially the Wood light. The simple test for porphobilinogen devised by Watson is pathognomonic for acute porphyria and may be used to differentiate the two types of porphyria. The determination of the type of porphyrin excreted is an elaborate procedure involving separation of the porphyrins chemically, and the identification by determination of melting points or by spectroscopy.

There is no effective treatment. Barbiturates must be rigidly avoided.

## CUTANEA TARDA TYPE OF PORPHYRIA

This chronic type of hereditary porphyria is characterized by photosensitivity which appears late in life (forty to fifty years of age). Brownish or violaceous skin pigmentation and bullae occur after exposure to sunlight. Abdominal and neurologic manifestations are absent. Hepatic dysfunction is common, and liver failure is often a cause of death. The urine may appear red and contains uroporphyrins of types I and III, but porphobilinogen is absent.

## HEREDITARY DEFECTS INVOLVING BILIRUBIN

Many of the obscurities surrounding the nature and origin of different types of jaundice have been resolved by the recent discovery that direct-reacting bilirubin is a glucuronide of bilirubin. The hepatic cell converts water-insoluble indirect-reacting bilirubin to the more soluble direct-reacting bilirubin by conjugating it with glucuronic acid (Fig. 67).

Two hereditary disorders associated with jaundice are due to metabolic defects in conjugation of bilirubin (see also p. 702):

1. *Congenital familial nonhemolytic jaundice with kernicterus*: a serious, rare hereditary condition in which the conjugating mechanism is deficient in the enzyme, uridyl transferase.

2. *Gilbert's disease*: a benign type of hereditary jaundice due to a deficit of the same enzyme.

## HEREDITARY METHEMOGLOBINEMIAS

### CONGENITAL METHEMOGLOBINEMIA

(IDIOPATHIC METHEMOGLOBINEMIA)

Congenital methemoglobinemia is a hereditary biochemical recessive defect of the eryth-

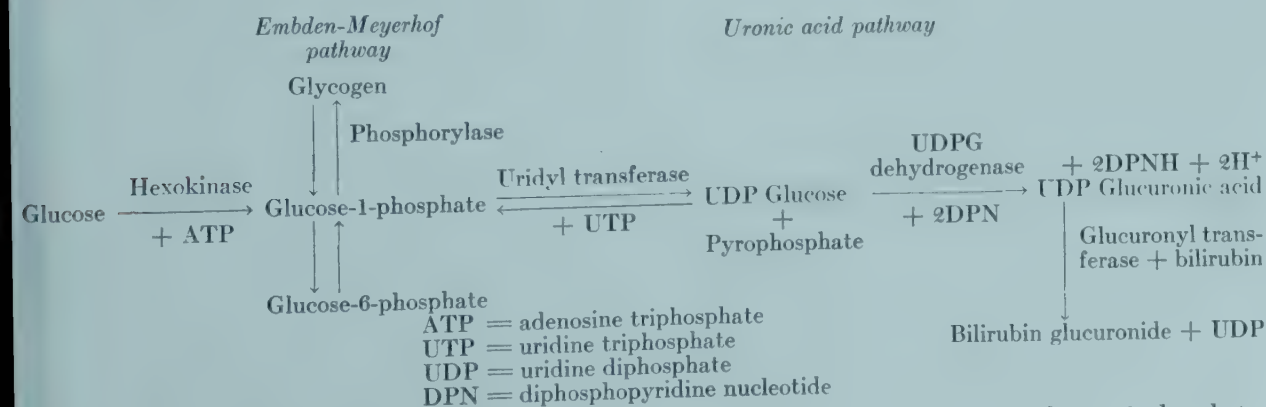

FIG. 67. Enzymatic steps in glucuronide synthesis along uronic acid pathway from glucose-1-phosphate.

rocyte characterized clinically by cyanosis resulting from the large amount of the intracellular hemoglobin which exists as methemoglobin. Hemoglobin iron functioning as a carrier of oxygen is always in the reduced or ferrous state ( $\text{Fe}^{++}$ ) in both oxygenated and deoxygenated hemoglobin. Methemoglobin iron is in the oxidized or ferric state ( $\text{Fe}^{+++}$ ) and is totally incapable of transporting oxygen. Methemoglobin is formed from deoxygenated hemoglobin by oxidation. Under aerobic conditions hemoglobin in aqueous solution is slowly and completely oxidized to methemoglobin. In intact normal erythrocytes methemoglobin is similarly and constantly formed. However, methemoglobin does not accumulate to more than 0.4 per cent of total hemoglobin in normal red blood cells, because it is reduced back to hemoglobin by a complex chain of enzymatic reactions almost as rapidly as it is formed.

The reduction of methemoglobin to hemoglobin in the intact erythrocyte is coupled with the oxidation of glucose or lactate. In the process of oxidizing glucose or lactate to pyruvate, coenzyme I (diphosphopyridine nucleotide) is reduced and is made available for the reduction of methemoglobin. A flavoprotein, the coenzyme factor, accelerates the reduction of methemoglobin by coenzyme I. In idiopathic methemoglobinemia there is a deficiency of the coenzyme factor, so that the accumulated methemoglobin comprises up to 40 per cent of the total erythrocyte pigment. In the absence of the coenzyme factor other reducing substances in plasma and red cells, e.g., ascorbic acid and glutathione, act as a secondary defense and reduce methemoglobin to a limited extent. In these patients methemoglobin shifts the oxygen dissociation curve of the blood to the left, an indication that the methemoglobin is present in all the erythrocytes.

Severe, persistent, diffuse cyanosis, most marked on the fingers, toes, lips, oral mucous membranes, conjunctiva and retinas, is the main clinical finding and is usually manifest at birth. The symptoms of respiratory or cardiac distress are mild in comparison to the intensity of the cyanosis. Dyspnea, tachycardia and palpitation may occur. Administration of oxygen does not relieve the cyanosis or other symptoms. In older persons fatigue, headache and poor tolerance to exercise are manifestations, but patients may be asymptomatic even after strenuous activity. Clubbing of the fingers does not occur. To compensate for the inert methemoglobin, sec-

ondary polycythemia with an accompanying reticulocytosis develops.

Freshly drawn blood has a chocolate color and does not regain its red color when oxygenated by shaking in air. The plasma is clear. Examined in a hand spectroscope after dilution with water (10 to 100 times), the characteristic dark absorption band of methemoglobin at 630 millimicrons is seen. Addition of 2 to 3 drops of 5 per cent potassium cyanide causes disappearance of the band. Sulfhemoglobin has an absorption band of 618 millimicrons, which is not abolished by potassium cyanide. Examination of the transilluminated ear lobe with the spectroscope may also reveal the characteristic absorption band. Despite adequate dietary intake the serum ascorbic acid content is low, as is the glutathione content.

Acquired methemoglobin may be caused by a variety of chemicals (p. 1379).

The capacity of ascorbic acid or methylene blue to reduce methemoglobin to hemoglobin is used both as a diagnostic test and as therapy. Large doses (200 to 500 mg.) of ascorbic acid taken daily in divided doses will reduce the methemoglobin content from 40 to about 10 per cent of the total pigment. Intravenous injection of methylene blue in a dose of 1 to 2 mg. per kilogram of body weight will cause prompt disappearance of both methemoglobin and cyanosis. From 3 to 5 mg. per kilogram of body weight daily in divided oral doses will keep a patient free from cyanosis. Ascorbic acid acts directly as a reducing agent, whereas methylene blue produces reduction of methemoglobin by acting in an enzyme system.

#### BIOCHEMICAL VARIANT OF IDIOPATHIC METHHEMOGLOBINEMIA

One patient has been observed who, though clinically indistinguishable from other patients with congenital methemoglobinemia, had no shift in the oxygen dissociation curve of his blood (Eder). However, there was good response to methylene blue and ascorbic acid.

#### HEMOGLOBIN M-METHEMOGLOBINEMIA

Persons with a genetically and chemically different type of methemoglobinemia have been identified in four generations of two different German families. "Cyanotic" persons with this trait appear well and are not inconvenienced physically, even though 15 to 25 per cent of their red blood cell pigment is methemoglobin. The biochemical abnor-

malinity resides in the globin fraction of the hemoglobin molecule. It is transmitted by an autosomal dominant gene, designated hemoglobin M. Hemoglobin M has a different spectral absorption curve from ordinary methemoglobin, and it does not cause a shift in the oxygen dissociation curve of blood. Ascorbic acid and methylene blue have no effect on hemoglobin M.

## CONGENITAL SULFHEMOGLOBINEMIA

Hereditary sulfhemoglobinemia is one of the rarest inborn errors of metabolism. A recent report of the disorder in a female infant is perhaps the first authenticated instance. Spectroscopic examination of the blood performed in the neonatal period because of persistent unexplained cyanosis revealed a sulfhemoglobin content of 1.0 gm. per 100 ml. (normal is less than 0.2 gm.). The infant's father, paternal grandfather, uncle and two cousins had similar values. At six months of age the infant was still cyanotic, but had grown and developed normally. The disorder was transmitted as a dominant characteristic.

Sulfhemoglobin is an inert pigment and does not transport oxygen. Hydrogen sulfide inhalation, ingestion of large amounts of sulfur and production of hydrogen sulfide in the bowel by bacterial action may cause sulfhemoglobinemia.

# The Newborn Infant

The duration of the newborn or neonatal period has been variously defined as the first two to four weeks after birth. The period is essentially that during which the organism is physiologically adjusted from an intrauterine to an extrauterine environment. Although the greatest changes and the largest incidence of morbidity and mortality occur in the first forty-eight hours of life (Fig. 68) and most

infants have begun to grow satisfactorily in their new environment by the fourteenth day, some of the adjustments are not complete by a month or more of age. Since most official morbidity and mortality statistics define the newborn period as the first month, it will be so considered in this section.

Directly or indirectly, much of the morbidity and mortality of the first forty-eight hours is related to factors arising before or during delivery. This is implicit in the term "obstetric death," used in some maternity clinics to include all stillbirths and all infant deaths within a week after delivery. This term, even more explicit than the more common one of "perinatal mortality," indicates the obstetrician's contribution to the condition of the infant during his early postnatal life. The joint activity of obstetricians and pediatricians in conferences on fetal and neonatal deaths and in preparation and analyses of statistics is especially fruitful.

Newborn premature infants are usually considered to have problems distinct from those of infants of full gestation, requiring nurseries where they can be given specialized care. Although the details of such care merit the section devoted to prematurity on page 306, it should be clearly understood that the prematurely born infant can be affected by any of the disease processes common to full term newborn infants. Because of this, no attempt has been made to describe separately all disturbances which may occur in premature infants.

FIG. 68. Distribution by fetal maturity and by postnatal age of all neonatal deaths in the Boston Lying-in Hospital during the 5 years 1945-1949, inclusive:

- ° 249 deaths among premature infants.
- 128 deaths among full term infants.
- 377 neonatal deaths

## PHYSIOLOGY OF THE NEWBORN INFANT

**Respiration. Tissue respiration.** Most evidence indicates that fetal blood has differences in oxygen affinity from maternal blood. These would allow fetal blood to become somewhat more saturated with oxygen than maternal blood at any given tension, and to release its oxygen to the fetal tissues with relatively little loss of tension. If these char-

acteristics are effects of fetal hemoglobin, they should persist in the infant's blood during and after the neonatal period. Most fetal hemoglobin is naturally replaced by adult hemoglobin by three to six months after birth. Since the artificial replacement of hemoglobin by transfusion immediately after birth does not obviously affect the infant's respiration,

fetal blood or fetal hemoglobin does not appear to offer significant advantages to the infant after birth.

The carbonic anhydrase activity of the erythrocytes is reduced in newborn and especially in premature infants. Such a deficiency must reduce the rate of carbon dioxide release and oxygen uptake in the lungs, but the clinical significance of this factor is also in doubt.

The young of all mammals seem able to withstand reduction or absence of atmospheric oxygen longer than adults of the same species. This feature appears related to the brief persistence after fetal life of an anaerobic type of carbohydrate metabolism and perhaps to a reduction of energy metabolism in general when oxygen supply is reduced. The human infant may thus survive anoxic episodes which would be lethal for the adult, but survival entails the risk of permanent damage to the central nervous system.

**Pulmonary respiration.** Although mammalian fetuses often exhibit rhythmic respiration-like movements in utero, this is apparently not a constant phenomenon. Therefore extrauterine respiration probably does not represent the simple continuation of an established process.

Some infants may begin breathing after birth as a result of exposure alone, just as they breathe more deeply, or cry, when further sensory stimuli are applied. Others, whose sensation or responsiveness is dulled by anesthesia, trauma or previous anoxia, may begin breathing only when chemical changes resulting from separation from the placenta reach a certain necessary level. Breathing under these circumstances is often irregular, gasping and of primitive character, but usually becomes more regular, rhythmical and effective as a result of improved oxygenation of the brain.

The first breaths require extra force to

overcome the cohesive state of the moist alveolar surfaces normal in uterine life, so that a negative pressure of 15 to 25 cm. of water may be needed for primary expansion. Since the newborn infant's thorax and diaphragm are capable of producing negative pressures of 40 cm. or more of water, there seems to be a wide margin of safety under ordinary circumstances. Normally, the lungs expand rapidly and completely in the first hour, sometimes with the first few breaths. Although the arterial blood is only about 50 per cent saturated with oxygen at the moment of birth, the level may exceed 90 per cent in most infants within thirty minutes; in almost all infants these higher saturations are attained within three hours.

Respiration in the neonatal period is normally accomplished by the diaphragmatic and abdominal musculature, with little thoracic movement. It is characteristically irregular, in both depth and frequency, and in normal infants may assume "cogwheel" or periodic patterns suggestive of pathologic states. Table 49 gives certain approximately normal mean values by which the breathing of the newborn infant can be compared with that of the adult. It will be noted that vital capacity and tidal volumes are roughly similar per unit of body weight. Minute volume and work of respiration in the infant are much greater per kilogram than in the adult, but are in keeping with the metabolic needs of the infant. The infant's heat production of 46 calories per kilogram per twenty-four hours, in contrast to twenty-three in the adult, is largely an expression of surface area differences (p. 290).

In the premature infant, weakness of the thoracic cage and respiratory muscles, incomplete development of alveolar structures, as well as elastic tissue and capillaries in the lungs, and feeble gag and cough reflexes all introduce added difficulties in the onset and

**Table 49. Adult and Neonatal Respiration**  
(Compared with Reference to Weight and Normal Heat Production)

	Actual (Mean)		Per Kilogram		Per 100 Cals.	
	Adult (70 kg.) (1600 Cals.)	Infant (2.5 kg.) (115 Cals.)	Adult	Infant	Adult	Infant
Vital capacity in ml.	4,800	140	68	56	300	120
Minute volume in ml.	6,000	500	85	200	370	435
Tidal air in ml.	500	15	7.1	6	31	13
Rate/minute.	12	34	(12)	(34)	(12)	(34)
Work (gm. cm./min.)	17,000	1,500	240	600	1,060	1,300

maintenance of respiration. The oxygen saturation of the arterial blood tends to be slightly lower in premature than in full term infants, even under normal circumstances. At usual saturations of 89 to 94 per cent, periodic breathing is more common than regular breathing. The momentary apnea associated with such periods may produce intermittent cyanosis. If the atmospheric oxygen is increased, there is usually increased ventilation and conversion of periodic to regular breathing. The explanation of this change is not known, nor is this regularization of breathing in itself an indication for oxygen administration if apneic spells can be terminated by gentle physical stimuli. It may be wiser to use oxygen only when nothing else will relieve cyanosis, and then only in the least effective concentration.

**Circulation.** The mechanics and timing of alterations in the human fetal circulation at birth are matters of dispute, although studies with roentgen cinematography have shown how these adjustments occur in other mammals.

In the fetal sheep oxygenated blood entering the right atrium from the inferior vena cava crosses through the foramen ovale into the left atrium with little admixture of venous blood from the superior vena cava. This oxygenated stream goes from the left ventricle into the ascending aorta and thus to the head and upper extremities. The larger part of the blood leaving the right ventricle appears to enter the descending aorta through the ductus arteriosus.

The major peripheral changes at birth are (1) the increased resistance beyond the descending aorta, (2) the decreased return through the inferior vena cava to the right atrium (both resulting from the removal of the placental circuit), and (3) the sudden decrease in resistance beyond the pulmonary artery as the lungs expand in breathing. The resultant relatively increased pressure in the left side of the heart tends to cause closure of the valve covering the foramen ovale. The muscular wall of the ductus arteriosus apparently constricts promptly (perhaps because of a local sensitivity to increased oxygenation of its blood), but the constriction may be incomplete for hours or days. Flow of blood through the temporarily persisting ductus may occur in either direction, depending upon changing pressure relationships. Murmurs are said to be absent in such infants even though the oxygen saturation and pressures measured at cardiac catheterization indicate considerable flow through the ductus. Exactly when and why complete constriction

occurs is not known; the anatomic closure of the ductus does not take place till the second or third month after birth.

Separation from the cord and placenta at birth removes about 100 cm. of vascular channels from the circulatory system. As a result, the heart has less work to do after than before birth, so that it does not grow so fast as the body in the first months of life. Thus standard relationships of cardiothoracic diameters cannot be applied to roentgenograms of the newborn infant. The fetal circulation involves at least as much work by the right ventricle as by the left, so that a right ventricular preponderance is a normal electrocardiographic finding.

Variability of the *pulse rate* is a characteristic of the newborn infant. For a few minutes after birth the average rate may be 150 to 180 per minute, but within an hour falls to 130 to 140, which remains the average for several weeks. During minimal activity the heart may beat as slowly as 80 per minute; during crying and exercise, more rapidly than 180 per minute.

Measurements of the *blood pressure* (see p. 822 for technique) differ with the method of registration. By auscultation mean systolic/diastolic readings at birth are 80/46 mm. of mercury; at one day, 85/40; and at ten days, 100/50. The mean systolic pressures measured by palpation are 10 to 15 mm. of mercury less, and by the "flush" method the readings are still lower.

Acceptable data regarding *circulation time* are still lacking. The *blood volume*, usually between 7.5 and 8.5 per cent of body weight at birth, may be slightly higher if the cord was not clamped until pulsation ceased or if blood from the cord was stripped toward the infant before clamping. Apparently 75 to 100 ml. of blood may be conserved for the infant by this procedure. Since the blood volume is rapidly readjusted by extrusion of excess plasma after birth, the result is a higher hematocrit value rather than a blood volume appreciably greater than that of infants whose cords were tied at once. There is no clear evidence that the gain or loss of this placental blood is of benefit in the newborn period. Its greatest effect may be upon the infant's store of iron, and thus not demonstrable until two or three months after birth.

**Peripheral circulation and capillary resistance.** The peripheral circulation of normal newborn infants is sluggish. The hands and feet are often cyanotic from the local stagnant anoxia even when arterial oxygen content is

normal, and local stagnation with seepage of plasma through capillary walls may explain the concentration of cells in heel- or finger-prick blood. Such samples may contain 10 to 20 per cent more cells and hemoglobin than those simultaneously obtained by venipuncture.

The capillaries of the skin are more coarse and profuse than those of the adult until several weeks after term birth, yet their resistance is relatively high. Petechiae appear when the skin of a premature infant of 1 kilogram (2.2 pounds) is subjected to negative pressure of about 150 mm. of mercury. Premature infants of 2 to 2.5 kilograms (4.4 to 5.5 pounds) do not show evidence of capillary rupture at negative pressures below 400 mm. of mercury, and the capillaries of "mature" infants weighing 3 kilograms (6.6 pounds) withstand 500 mm. negative pressure. The resistance appears to decline after birth to a critical pressure between 250 and 400 mm.

The susceptibility of the premature infant to hemorrhage is presumably caused by the increased fragility just mentioned, by vascular permeability associated with occasional anoxia, and by impairment of the clotting mechanism, as from inadequate conversion of vitamin K to prothrombin by the immature liver.

**Blood Formation.** The morphology of the blood during neonatal life is described on page 922. The hemoglobin and erythrocyte values rise slightly during the first two days. Readjustment of blood volume is partly responsible for this increased concentration, but the reticulocytosis (3 to 6 per cent) and the occasional nucleated red blood cells normally present indicate that blood formation is active. After the second day, concentrations of hemoglobin and erythrocytes decrease, especially during the second and third weeks after birth. The hemoglobin falls more rapidly than does the erythrocyte count.

**Icterus Neonatorum and Hepatic Function.** About 50 per cent of all newborn infants become visibly jaundiced. This physiologic icterus usually appears on the second or third day of life, regresses by the seventh, and disappears by the fourteenth. The excess pigment responsible for such jaundice has not passed through the hepatic cells and gives the "indirect" or "delayed" reaction in quantitative measurement of serum bilirubin. Since its concentration is already slightly elevated in the cord blood and reaches its peak by the third to fifth day, before the erythrocyte

count has begun its most rapid fall, the hyperbilirubinemia of physiologic icterus apparently results from impairment of bilirubin removal rather than an increase in the amount to be removed.

It now appears that many instances of jaundice presumed to be physiologic are actually the result of pathologic hyperbilirubinemia. Data formerly accepted as indicating the range of serum bilirubin concentrations encountered in physiologic jaundice therefore require revision. Even the accepted concept that icterus neonatorum is especially common after premature birth and the inference of "physiologic hepatic immaturity" await such revision. Tests of hepatic function in newborn infants have not demonstrated much impairment, even after premature birth. There is a slower clearance of sulfobromophthalein by newborn premature than by newborn term infants, and the relative hypoproteinemia, hypoprothrombinemia and hypoglycemia of the premature infant all suggest imperfectly developed hepatic functions not otherwise demonstrable.

**Digestive Tract.** After delivery the digestive tract of the newborn infant is rapidly converted to an actively functioning system. This transition is enhanced by a relatively large absorptive surface, with numerous secretory glands, and a relatively thin and lax muscular coat. This latter feature favors distention, which may be induced by the swallowing of large quantities of air, which begins at birth. The usual advance of air to the descending colon within the next three hours makes its roentgen demonstration diagnostically useful in suspected intestinal obstruction. Food moves relatively slowly through the upper gastrointestinal tract, portions of a single feeding often remaining in the stomach as long as eight hours, but material may traverse the entire large bowel of the newborn in two to four hours.

With the exception of amylase, *enzymes* are present in the gastrointestinal canal early in fetal life. The pH of gastric contents at birth is in the range of neutrality, but between five and twenty-four hours after birth the reaction becomes remarkably acid, with an average pH of about 1.5. After this the acidity decreases to a temporary low level which is reached between the first and second weeks of life.

The intestinal tract at birth contains from 60 to 200 gm. of greenish-black viscid material known as meconium. It contains relatively little nitrogen, most of which is non-

Table 50. Approximate Caloric Requirements of Premature and Term Infants after the First Week of Life

Daily Caloric Requirements per Kg. of Body Wgt.

Fecal loss.....	20	10
Maintenance.....	90	80
Weight gain.....	30	20
Total.....	120 (55/lb.)	100 (45/lb.)

protein, some lipids and, as the largest component, a mucopolysaccharide. In infants who are secretors of the specific polysaccharides of the A and B blood groups, the meconium contains these substances in high concentration. Meconium is apparently largely composed of the residue of mucous secretions of the fetal digestive tract after their digestion by the proteolytic enzymes. Passage of meconium from the rectum usually begins during the first ten hours, and most meconial characteristics disappear from the stools by the fourth day after birth. There may then be a few greenish, moist, "transitional" stools before the defecations become characteristic of infancy.

The digestion and assimilation of proteins and simple sugars are efficiently performed by both term and premature infants. Higher carbohydrates such as starches are not well digested, owing to insufficient enzymes. Fats seem to be digested without difficulty, but absorption of split fats appears to be relatively inefficient. The premature infant may absorb a higher percentage of fat from human than from cow's milk. The nutrition of premature infants is hampered by some degree of impaired assimilation and by their relatively rapid growth.

**Metabolism.** The surface area of the newborn infant is large in comparison to his weight, so that the *basal metabolism* per kilogram is higher than that of the adult. By the more applicable standard of surface area, the average infant's heat production is about 25 calories per square meter per hour during the first week of life. Corresponding figures for the child of two years and for the adult are, respectively, about 48 and 38 calories. An

increase of 10 to 20 per cent in heat production occurs by the end of the first month as more calories are added to the basal requirements for the needs of growth. There are inadequate data concerning the metabolism of premature infants during the first week of life, but beyond that age their heat production is usually lower per unit of surface area than that of term infants.

The limited data available on measurements of the *respiratory quotient* provide only an indication of the pattern of caloric combustion. The higher respiratory quotients usually found immediately after birth suggest that the fetus obtains energy mainly, if not entirely, from carbohydrate. Within the first few hours the metabolic mixture appears to be about two-thirds carbohydrate and one-third fat, but by the second day it consists entirely of fat. Apparently the available glycogen is rapidly consumed. After maternal lactation has become sufficient for weight gain, or by the sixth or seventh day, fat becomes the source of about 60 per cent of energy, and carbohydrate of 40 per cent. This sudden utilization of fat in early postnatal life is accompanied by large increases in concentration of the blood lipids. The few data from premature infants suggest that after the first week or two, relatively more of their energy comes from carbohydrates than is the case with infants born at term.

The *caloric requirements* of premature and term infants in general are lower in the first week of life than after postnatal growth has been established (see Table 50).

The relatively large surface of premature infants, the low heat production, their inactivity and the lack of subcutaneous fat resulting in poor insulation contribute to a tendency toward hypothermia. Conversely, the immature sweating mechanisms of the premature infant favor hyperthermia in overheated environments or when the escape of body heat is prevented by too many wrappings. An unsettled question of importance is whether body temperature of 37° C. (98.6° F.) is of greater advantage than stabilization at a somewhat lower level. A lower requirement for oxygen at reduced body temperatures is a theoretic possibility, but has not been proved. Nevertheless the satisfactory clinical status of many small premature infants maintained with rectal temperatures of 35° C. (95° F.), or even lower, has been demonstrated repeatedly.

**Acid-Base Balance.** In both term and premature infants perhaps the outstanding char-

acteristics of acid-base balance are the wide ranges of blood hydrogen ion content and of concentrations of related plasma components, and the tendency toward a metabolic acidosis. These features are more pronounced and tend to persist longer in premature infants than in term ones. Concentrations of chloride ions and of other strong acid radicals may be increased in the plasma. Whether unusual accumulations of lactic and pyruvic acids resulting from incomplete glucose metabolism ("anaerobic metabolism") account for all the increase of strong acids remains to be established. If this were so, it would indicate that the metabolic pattern of the fetus persists for some time, particularly after premature birth. Whatever the explanation for the slightly lowered pH of the blood in infants born at term, the acquisition of a normal pH within twenty-four hours indicates that the initial metabolic acidosis is promptly compensated by adjustments which may be both renal and respiratory; this compensation does not occur so quickly in infants born prematurely. Since low pH levels are regularly observed in premature infants in apparently satisfactory clinical condition, there is no proof that this chemical status is harmful.

**Water balance and renal function.** The infant's body contains relatively more water at birth than in later infancy. Since the degree of hydration is still greater in earlier fetal life, many small premature infants are obviously edematous at birth. The relatively high content of sodium as compared to that of potassium in the body of the newborn and fetus suggests a large extracellular fluid space. The physiologic weight loss of 6 to 10 per cent of body weight during the three to five days after birth is accounted for in part by loss of vernix from the skin and of meconium from the bowel, and by metabolism of body stores of glycogen, fat and protein, but the largest factor is loss of body water. Infants who receive no fluid for three days after birth may lose more than 10 per cent of body weight. Loss of so much water may be accompanied by hemoconcentration, which may not be harmful and is promptly rectified by the administration of fluid on the fourth day.

Since adults similarly deprived of fluid conserve enough body water by secreting a urine of high concentration to prevent hemoconcentration, the larger water loss of the newborn infant is an example of one limitation in renal function. The maximum concentration of urine (about 700 milliosmols per liter) is apparently no greater in term than

in premature infants, and increase in this function is more closely related to postnatal than conceptional age. Since the food of infants is fluid, this limitation in renal concentration during the first two to four weeks after birth is not of critical significance under usual circumstances, though it assumes great importance in diseases accompanied by excessive loss of body water and in the application of therapy to their repair. Conversely, the kidney is able to excrete an excessive load of water by dilution of the urine.

The more specific tests of renal function measuring glomerular filtration rate, renal plasma flow and tubular excretion have provided data perhaps more interesting to the renal physiologist than applicable by the clinician. In general, these functions are all reduced in the term infant and somewhat further reduced in the premature one. Performance comparable to that of the adult kidney appears to be reached a year or two after birth. But the bases for comparison of data from infants and adults are undetermined; if referred to surface area, there is a wide scatter of the data obtained from normal infants at any age, many measurements being within the adult range. The responses of infants less than one month of age to such tests generally show further limitation of function, but with no less scatter, and there is considerable overlap of the results from premature and term infants. Hence the guidance of the laboratory in the diagnosis and therapy of newborn infants with suspected renal impairment is limited. Even the blood concentrations of nonprotein and urea nitrogen are difficult to evaluate in the first week or two after birth, since their levels normally vary with protein and water intake. During the "hydropenia" of the second or third day after birth, concentrations of 60 and 30 mg. per 100 ml., respectively, may be attained. The general belief that albumin is normally present in the urine of newborn infants is probably based on falsely interpreted tests. A relatively high percentage of nitrogen in the infant's urine is in the uric acid fraction; it may be deposited as "uric acid infarcts" in the kidneys and as pink urates on the diaper.

**Endocrine Glands.** Endocrinologic alterations accompany the transition from a dependent intrauterine status to an independent extrauterine one. Not only must the glands of the infant take over new responsibilities, but also there are actual and potential effects from *maternal hormones*. These may persist

after placental transmission (and production), or the infant may react to the sudden release from their influence. Most infants of both sexes have hypertrophy of the breasts during the first week of life, and many have some secretion of so-called witch's milk. These changes, observed less frequently in prematures, are apparently due to two hormones. The first appears to be an estrogenic substance of placental and ovarian origin, which produces the mammary hypertrophy and is also responsible for other changes such as hypertrophy of the vulvar tissues, vaginal discharge and desquamation, and occasional uterine bleeding in female newborn infants and transitory prostatic metaplasia in males. The second hormone, prolactin, comes from the anterior pituitary and is responsible for the temporary lactation in the infant, but whether its source is the mother's or the infant's pituitary is not known.

The *adrenal glands* are proportionately much larger at birth than at any time thereafter, representing 0.2 per cent of total body weight as compared to 0.01 per cent of adult body weight. The enlargement is almost entirely in the inner cortical zone. Involution of this tissue begins immediately after birth, reaching its height in the second week, but continuing for a period variously estimated to be two weeks to a year. This involution has been interpreted as a discarding of a "masculinizing" or androgenic tissue developed to protect the fetus against the rising tides of maternal and placental estrogens, but there is no elevation of 17-ketosteroid excretion in the urine of newborn infants to support this hypothesis.

Little is known about the various activities of the *pituitary gland* in the newborn infant, but less oxytocic and antidiuretic activity can be obtained from glands removed from newborns than from those of adults. The *thyroid gland* is well developed at birth, is normally somewhat hyperemic and contains adequate colloid. Its secretion is apparently provided to the fetus for several months before birth and perhaps may be available to the mother if her supply of thyroid hormone is deficient. Maternal thyroid hormone may also cross the placenta, since the clinical cretinism of athyrotic infants may be masked for some time after birth.

The *parathyroid glands* and the islet cells of the *pancreas* have received less attention in regard to their characteristics in neonatal life than in regard to the fetal-maternal in-

terchange of hormones in utero. Although there may be a transient hypoparathyroidism, the temporary increase of serum phosphate and decrease of serum calcium in newborn infants may be related to renal as well as to parathyroid factors. The islet tissue content of the pancreas of newborn infants is variable. Peculiarities of insulin secretion have not been discovered, although it has been supposed that an increased production occurs in the offspring of diabetic women as a result of fetal exposure to hyperglycemia. Passage of either parathyroid hormone or insulin between the human mother and her fetus has not been demonstrated, but from observations on other mammals may be presumed to occur.

**Immunity.** Although the newborn infant acquires certain antibodies by placental transfer, resistance to infection is generally weak and infectious processes are poorly localized. It is possible that the production of antibodies is less efficient than in the older person, although this apparent disability may be associated with the presence of transient passively acquired immunity rather than the immaturity of immunologic response mechanisms per se. In human beings the transplacental acquisition of antibodies is much greater than their ingestion in colostrum and mother's milk.

Present knowledge of specific infectious agents and of immunologic responses can be summarized as follows:

1. Antibodies to diphtheria, tetanus and the viruses of measles, mumps and smallpox, and probably those of poliomyelitis and the common cold, will, if present in the mother, pass the placenta in sufficient quantity to exert a passive protective effect of some degree but brief duration. In the prematurely born infant less reliance can be placed on the effectiveness of such protection.

2. To several common infectious agents the newborn infant appears to receive no transplacental immunity, and even to have a special susceptibility. These include *H. pertussis*, streptococci, staphylococci and such organisms as *E. coli* which do not ordinarily cause disease in older persons.

3. Certain viruses and bacteria which cause severe diarrheal disease among newborn infants apparently either are not pathogenic for older persons or produce in them different and relatively less severe manifestations.

4. The standard immunization procedures may result in slightly less rapid antibody pro-

duction if begun during the first two months after birth (see p. 141 for schedule for immunization).

5. Protection of newborn infants from contact with infection is a more reliable means for the prevention of disease than dependence upon transplacental immunity or upon antimicrobial prophylaxis. Since infec-

tion in newborn infants may not only be relatively inapparent, but also easily transmitted, such prevention of contact with infection must be directed against contact with other infants as well as adults.

## THE HISTORY IN NEONATAL PEDIATRICS

The medical history of the neonate should (1) be aimed at uncovering factors which may lead to early identification of diseases in which disability or mortality may be prevented by prompt treatment, (2) lead to the anticipation of conditions which may be of importance later to the infant, and (3) uncover possible etiologic factors which may help identify and explain to parents any pathologic condition regardless of its immediate or future significance. Parents are reassured as to the competence and interest of their child's physician when he diagnoses inapparent disease in the newborn period and when he offers explanation for apparent disease.

Although ideal, it is impossible under ordinary circumstances to take the time to record a detailed family history, including that of the pregnancy, on every newborn infant. It should be obtained, however, whenever there is any untoward circumstance in the newborn or any known familial disease, and it should be routine in all instances to inquire about the existence of genetically determined disease.

**Genetic Factors.** Congenital anomalies, inborn errors of metabolism, certain endocrinopathies and a variety of specific disease states identifiable in the newborn period are or may be genetically determined.

Their occurrence in siblings or direct ancestors should suggest the possibility of the same defect in the newborn infant. Since most of these conditions are not immediately obvious on physical examination, they may be missed unless a careful history is obtained. Because many parents are aware not of the name or existence of these genetically determined diseases, but only of one or more of their manifestations, specific inquiry should be made about any disease affecting more than one blood relative. (See Prenatal Factors in Disease, p. 234; Inborn Errors of

Metabolism, p. 250; Diseases of the Blood, p. 930; The Genitourinary System, p. 1005; Mental Deficiency, p. 1129; The Nervous System, p. 1063; The Endocrine System, p. 1150; Diabetes Mellitus, p. 1205; The Bones and Joints, p. 1226; The Muscles, p. 1264; The Skin, p. 1274; The Eye, p. 1329; and Allergy, p. 1304.

**Maternal Factors.** *Maternal age* is a factor in fetal and neonatal mortality. The lowest neonatal mortality rate (about 2 per cent) occurs in infants of mothers twenty to thirty years of age; it is almost doubled if the mother is forty to forty-five years, and quadrupled if she is forty-five and over. The neonatal mortality is also high if the mother is less than fifteen years of age.

*Maternal illness* early in pregnancy, while the embryo is undergoing organogenesis, can result in serious maldevelopment (see p. 242). Severe illness or trauma at any time during pregnancy may cause fetal death or premature onset of labor. Certain maternal infections, notably syphilis, toxoplasmosis and Coxsackie virus group B, may infect the fetus. Maternal diabetes (perhaps even in the prediabetic state), and possibly paternal diabetes, may affect the fetus and infant profoundly (p. 1214). The dangers of incompatibility between maternal and fetal blood groups are discussed on page 956. Platelet antibodies associated with maternal thrombocytopenic purpura may be transferred across the placental membrane to cause transient platelet deficiency in the infant. Likewise, transient neonatal myasthenia gravis may be seen in the infants of mothers with the disease without apparent relation to the severity or degree of control of the maternal myasthenia. Drug addiction by the mother may result in alarming withdrawal symptoms in the infant such as tremors and convulsions. Maternal hyperthyroidism may result in a transient hyperthyroid state of the

infant. The toxemias of pregnancy presumably disturb the infant directly and also indirectly by influencing obstetric management. The direct effects appear to be related to an intrauterine anoxia associated with placental infarction, separation and hemorrhage rather than to any toxic substance reaching the fetus. Lactation tends to be less successful after delivery in the toxemic woman. The incidence of prematurity, stillbirth and neonatal deaths is twice as great in infants from toxemic mothers as in those born to healthy ones.

*Obstetric factors* are of understandable importance when one considers that neonatal mortality is greatest during the first twenty-four hours after delivery. Rupture of membranes earlier than twenty-four hours before delivery carries a risk of infection of the intrauterine contents which may justify antibacterial treatment of the infant. Prolonged labor definitely increases the "risk of being born." The risk of neonatal death in uncomplicated labors lasting twenty-four hours or less is approximately 0.32 per cent; it increases sixfold in labors lasting over twenty-four hours, and twentyfold, to 6 per cent, in those over thirty hours. A tumultuous short labor, with a precipitate delivery, is also unfavorable for the infant. Placental separation, abnormal implantation or compression of the cord increases the possibility of fetal anoxia. Fused placentas in multiple pregnancies may considerably affect the circulation and general development of the fetus.

Some information of diagnostic value may be obtained from the type and amount of amniotic fluid. A brown or muddy fluid suggests that meconium has been passed during an episode of fetal anoxia. Polyhydramnios may occur with toxemia and maternal diabetes or for unexplained reasons; its presence should also suggest the possibility of interference with fetal swallowing, as by an esophageal atresia. Conversely, congenital aplasia or hypoplasia of the infant's kidneys is often accompanied by a reduced amount of amniotic fluid, presumably because fetal urine has not been formed.

Although the relative danger of any type of delivery, normal or operative, depends upon the skill of the obstetrician, statistics show that an increased hazard accompanies certain methods. Obviously, this results not only from the method, but also from the accompanying circumstances which dictated its use. The study from Chicago by Bundesen, Potter

**Table 51. Neonatal Mortality Rate per 1000 Live-born Infants by Various Methods of Delivery**

Spontaneous vertex delivery . . . . .	24.7
Low forceps . . . . .	7.9
Mid and high forceps . . . . .	29.7
Cesarean section . . . . .	35.7
Breech extraction . . . . .	39.6
Version and extraction . . . . .	118.2
Total mortality rate by all methods of delivery	21.5

and others showed a neonatal mortality rate per 1000 live-born infants as above.

Neonatal deaths following deliveries by mid and high forceps, breech extraction and version are likely to be related to intracranial injury; those following other forms of delivery are more apt to be due to anoxic disturbances.

Infants born by cesarean section present problems which may be related to the unfavorable obstetric circumstance which necessitated the operation or to prolonged maternal anesthesia. The impression prevails, however, that even in the absence of these factors, delivery through the abdomen carries a greater risk than delivery through the birth canal. Though the neonatal mortality from elective cesarean sections performed at term by a skilled obstetrician with an experienced anesthetist is extremely low, occasional deaths do occur. Hyaline membrane syndrome (p. 324) is the condition most frequently associated with an unfavorable outcome. Moreover, perhaps 5 per cent of infants so delivered have some degree of respiratory difficulty for a day or two after birth. The infant delivered by cesarean section should be kept under close observation during the first few days of life.

Anesthesia and analgesia affect the fetus as well as the mother. The skilled use of these agents consists in avoiding severe fetal narcosis while securing the benefits of gentle and unhurried delivery. Even skilled use often results in a mildly depressed infant whose crying and breathing may be delayed a minute or two and who may be somewhat inactive for several hours. Such infants are of less concern than those in whom an apparently similar status has been produced by central nervous system impairment from anoxia or trauma. When anesthesia and analgesia are carelessly used, or when their milder effects are added to already unfavorable fetal circumstances such as prematurity, anoxia or trauma, the consequences are clearly dangerous.

Finally, a vaguely understood but real factor in the maternal history is known under the loose term of "reproductive inefficiency." Some women do not easily become pregnant. They, and others, frequently abort spontaneously in early pregnancy or carry infants to a later unexplained intrauterine death, to pre-

mature or to postmature birth. Any newborn infant whose mother has such an unfavorable background should receive careful medical attention, since an increased likelihood of neonatal morbidity and mortality is one more evidence of what is termed reproductive inefficiency.

## THE PHYSICAL EXAMINATION IN NEONATAL PEDIATRICS

The purposes of the initial physical examination of the newborn as soon as possible after delivery are twofold: to detect abnormalities and to establish a baseline for subsequent examinations. Since examination in the mother's presence affords an ideal opportunity for initiating the anticipatory guidance which should be an integral part of all periodic health examinations, a second one should be performed twelve to twenty-four hours later when she has had a chance to rest from the rigors of her labor. At this time even minor anatomic variations which seem insignificant should be explained, because the mother may be disturbed if she has to point them out or if the physician does not appear to give them adequate consideration. This procedure carries the possibility of unduly alarming otherwise unworried parents unless it is carefully and skilfully done. No infant should be discharged from the hospital without a final examination, since certain abnormalities, particularly heart murmurs, frequently appear or disappear in the immediate neonatal period, or there may be evidence of acquired disease. Pulse and respiratory rates, weight, length, head circumference and dimensions of any visible or palpable structural abnormality should be recorded at these three examinations.

Many of the physical and behavior characteristics of the newborn infant are described on page 28 and many physiologic attributes on page 286. These sections should be consulted before reading this one, for repetition has been avoided so far as possible.

The examination of the newborn infant requires patience, gentleness and flexibility in standard routines of procedure. Thus, if the infant is quiet and relaxed when first approached, palpation of the abdomen or auscultation of the heart may best be introduced before other more disturbing manipulations.

The **general appearance** of the infant tells much. Physical activity may be absent in the relaxation of normal sleep or depressed by central disturbance; the infant may be lying with motionless extremities because all his energies are conserved for the effort of difficult breathing, or he may be vigorously crying with accompanying activity of arms and legs. Coarse, tremulous movements with ankle or jaw clonus are more common and of less significance in newborn infants than at any other age. Such movements tend to occur when the infant is active, whereas convulsive twitchings usually occur in an otherwise quiet state. Nutritional status is evidenced by weight and length and by wrinkling or plumpness of the body surfaces. An appearance superficially suggesting good nutrition may be produced by edema, frequently present in premature infants. There may or may not be pitting after pressure, but the fingers and toes will lack the normal fine wrinkles over the knuckles because they are puffed out with fluid. Edema of the eyelids is a common result of irritation from silver nitrate.

**Skin color** is important. Vasomotor instability and sluggishness of peripheral circulation are revealed by deep redness or purple lividity in the crying infant, whose color may darken profoundly with the closure of the glottis preceding a vigorous cry, and by the harmless cyanosis of the hands and feet, especially when these are at all cool. Mottling is another example of general circulatory instability. An extraordinary division of the body from forehead to pubis into a red half and a pale half has been aptly named a *harlequin color change*. This is transient, apparently harmless, and inadequately explained. Significant cyanosis may be masked by pallor in circulatory failure; on the other hand, the relatively high hemoglobin content of the first few days and the thin skin may combine to produce an appearance of cyanosis when the

arterial oxygen saturation is adequate. Localized cyanosis is differentiated from ecchymosis by the momentary pallor which follows pressure. The same maneuver is also helpful in demonstrating icterus, which may be of considerable degree, but pass unnoticed if the skin is suffused with blood.

The vernix and lanugo hair are described elsewhere (p. 29), as are the common transitory capillary hemangiomas of the eyelids and neck (p. 1274). Slate-blue, well demarcated areas of pigmentation are seen over the buttocks, back and sometimes other parts of the body in about half of all Negro infants and occasionally in white ones. These have no certain anthropologic significance in spite of their designation as mongolian spots; they tend to disappear within the first year. The vernix, skin and, especially, the cord may be stained a brownish-yellow if the amniotic fluid has been colored by passage of meconium during or before birth, usually because of intrauterine anoxia. The skin of the premature infant is thin and delicate and tends to be deep red; in extreme degrees of prematurity the appearance is almost gelatinous. The nails are rudimentary at very premature birth; conversely, they may protrude beyond the finger tips in infants born past term.

The skull may be molded, particularly if the infant is the first born and if the head has been engaged for a considerable time. The parietal bones tend to override the occipital and the frontal bones. The head of an infant born by cesarean section or from a breech presentation is identified by its characteristic roundness. The suture lines and the size and tension of the anterior and posterior fontanels should be determined digitally. There is much variation in the size of the fontanels at birth; if small, the anterior fontanel usually tends to increase during the first few months of life. Soft areas (craniotabes) which have the resilience of a ping-pong ball are occasionally found in the parietal bones at the vertex near the sagittal suture; they are usually inconsequential, but, if they persist, should be differentiated by roentgenographic examination from lacunar skull (p. 1230) and from other causes of craniotabes. Soft areas in the occipital region suggest the irregular calcification and wormian bone formation associated with osteogenesis imperfecta, cleidocranial dysostosis, cretinism and occasionally mongolism. Transillumination of the skull in a dark room will rule out hydranencephaly (p. 1093) or porencephaly (p. 1075).

The face may be asymmetric from fetal posture (p. 1250); when the jaw has been held against a shoulder or an extremity during the intrauterine period, the mandible may deviate strikingly from the midline. The skull of the premature infant may suggest hydrocephalus because of the relatively larger brain growth as compared to that of other organs. The eyes are often opened spontaneously if the infant is held up and tipped gently forward and backward. This is undoubtedly a result of labyrinthine and neck reflexes. This maneuver is more successful than that of forcing the lids apart to inspect the eyes. Focus and equality of pupils are normally established some weeks after birth. Conjunctival and retinal hemorrhages do not by themselves have serious significance. Deformities of the pinna of the ears are seen occasionally. Unilateral or bilateral preauricular papillomas occur fairly frequently; if pedunculated, they can be ligated tightly at the base, and dry gangrene and slough will result. The tympanic membrane is easily visualized otoscopically through the short, straight external auditory canal and is normally dull in appearance. There may be a slight obstruction of the nose from an accumulation of mucus in the narrow nostrils. The mouth may rarely show precocious dentition, with supernumerary teeth in the lower incisor position or aberrantly placed; these teeth are shed before the deciduous ones erupt. Premature eruption of deciduous teeth is even more unusual. On the hard palate on either side of the raphe may be temporary accumulations of epithelial cells called Epstein's pearls. Retention cysts of similar appearance may also be seen on the gums. Both disappear spontaneously, usually within a few weeks of birth. Clusters of small white or yellow follicles or ulcers on an erythematous base may be found on the anterior tonsillar pillars, most frequently on the second or third day of life. Their cause is unknown, and they clear without treatment in two to four days. There is no active salivation. The throat of the newborn infant is hard to visualize because of the arch of the palate; this, however, should be clearly visualized because of the possibility of easily missed clefts of the posterior palate or uvula. The small tonsils give no clue to the size to be attained during later lymphoid tissue growth. The tongue appears relatively large; the frenulum may be short, but rarely, if ever, is this a reason for cutting it. Occasionally the sublingual mucous membrane forms a prominent fold. The cheeks have a fullness on both

the buccal and the external aspects due to the accumulation of fat which makes up the sucking pads. These pads, as well as the labial tubercle on the upper lip, disappear when the suckling days are over. The neck appears relatively short. Abnormalities are not common; they include goiter, cystic hygroma, branchial cleft rests and lesions of the sternocleidomastoid muscle, which are presumably traumatic (p. 1264).

Almost as much can be learned about the lungs by observation of breathing as by auscultation and percussion. Variations in rate and rhythm are characteristic. The rate may vary from 20 to 100 times a minute in normal infants, depending largely on their physical activity, state of wakefulness or presence of crying. However, the pattern of fluctuations of the rate measured while the infant is quiet carries prognostic significance. Miller divides newborn infants into three groups, depending on the trend of their resting respiratory rates (see Table 52). The premature infant may normally breathe with a Cheyne-Stokes rhythm or with complete irregularity, but, in any stage of maturity, irregular gasping, sometimes accompanied by spasmodic movements of the mouth and chin, strongly indicates serious impairment of respiratory centers. The breathing of newborn infants is almost entirely diaphragmatic, with the result that the soft front of the thorax is commonly drawn inward during inspiration and the abdomen simultaneously protruded. If the baby is quiet, relaxed and of good color, this "paradoxical movement" is not necessarily a sign or a cause of insufficient ventilation. On the other hand, labored respiration is important evidence of abnormal pulmonary ventilation, pneumonia or other mechanical disturbance of the lungs. The interspaces usu-

ally draw in during inspiration when the mechanical difficulty is that of either too much or too little air in the lungs, so that the differentiation between atelectasis and emphysema must be made on the size and shape of the chest and on the percussion note. The weak groaning or whining cry which often accompanies expiration in severe disturbances of respiration is a most unfavorable prognostic sign. A method of "retraction scoring" which, along with the respiratory rate and the presence or absence of cyanosis, affords a convenient gauge of respiratory difficulty in newborn infants is illustrated in Figure 69.

Percussion may be more informative than auscultation, because in the small total area of the lungs breath sounds from an adjoining region may be heard as though directly under the stethoscope. Normally, the breath sounds are bronchovesicular. Suspicion of diminished breath sounds should always be verified by inducing deeper breathing and, if a local area is suspicious, altering the position of the infant's head and body before final decision. This latter maneuver also applies to suspected percussion dullness. The fine, crackling rales of early pneumonia in the newborn may be heard only at the end of the deep inspirations induced by crying.

The size of the heart is estimated with some difficulty, owing to normal variations in the size and shape of the chest. There may be transitory murmurs; conversely, congenital malformations may not at once produce the murmur which will be present later. According to Richards, there is only a 1:12 chance that a murmur heard at birth represents congenital heart disease. Evaluation of the heart by roentgenogram and electrocardiogram is desirable when the possibility of significant

Table 52. First-Week Deaths According to Birth Weight and Respiratory Group\*

Respiratory Group	1001-1500		Birth Weight—Gm.				Total	
	Born	Died	1501-2000		2001-2500		Born	Died
			Born	Died	Born	Died		
I.....	2	0	20	0	104	0	126	0
II.....	2	0	30	0	90	0	122	0
III.....	31	11	42	10	29	2	102	23

Group I: Infants who, while quiet, breathe approximately 40 times a minute from birth on without fluctuations greater than 15 per minute.

Group II: Infants whose respiratory rates are high (usually over 60 per minute) the first hour, show no significant increase after the first hour and subsequently decrease to normal levels, usually within 4 to 48 hours after birth.

Group III: Infants whose respiratory rates show a significant increase (15 per minute or more over the mean for the first hour) during the first 48 hours.

Infants with major anomalies or with hemolytic disease of the newborn were excluded.

\* Adapted from H. C. Miller: Studies of Respiratory Insufficiency in Newborn Infants. Pediatrics, 20:817-26, 1957.

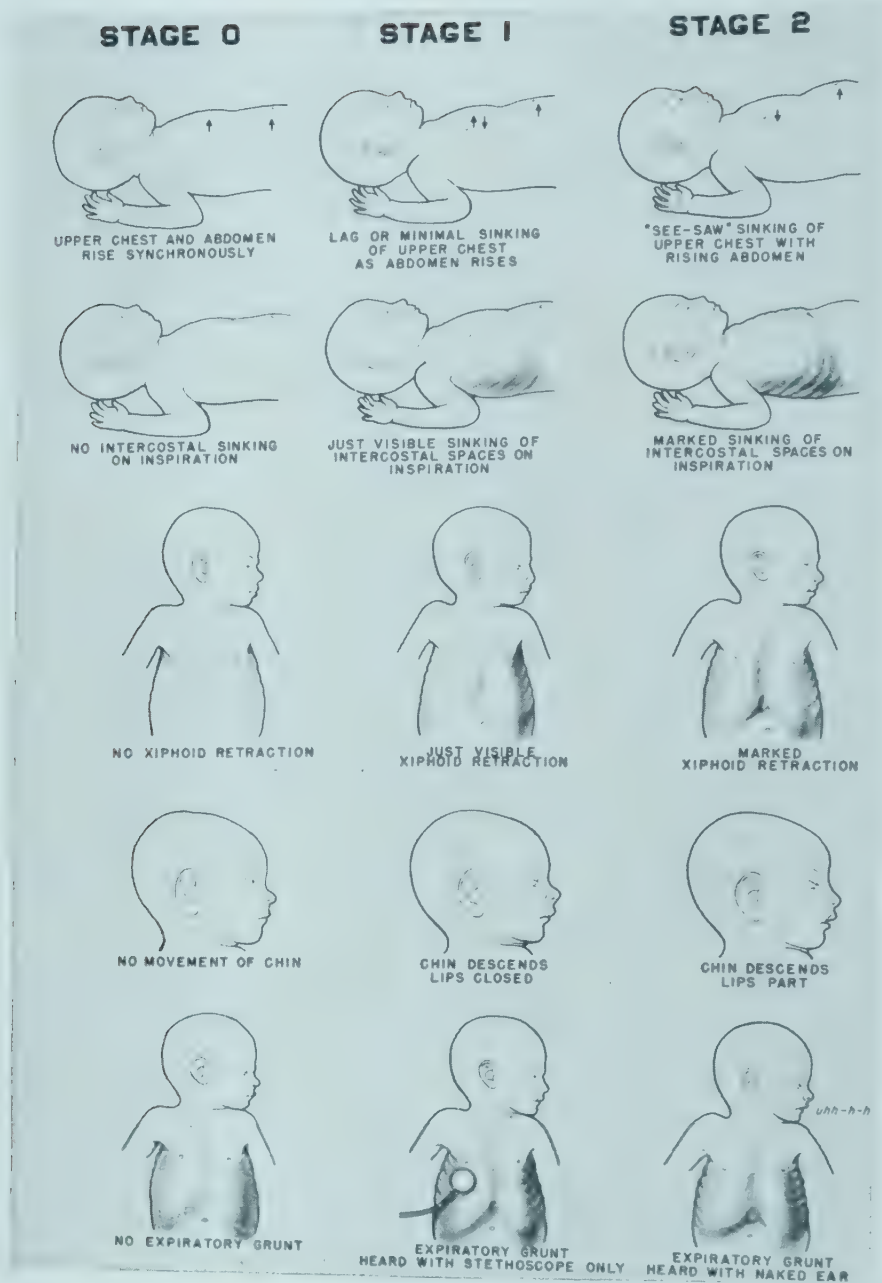

FIG. 69. Retraction scoring. The "retraction score" is computed by adding the values (0, 1 or 2) assigned to each criterion at the time of a single observation. A score of zero indicates no respiratory distress; a score of 10 indicates severe respiratory distress. (Modified from Silverman and Andersen: *Pediatrics*, 17: 1, 1956.)

lesions exists. The pulse may vary normally from 90 per minute in relaxed sleep to 180 during activity. The still higher rate of paroxysmal tachycardia may be counted better on an electrocardiogram than by ear. **Blood pressure** measurements (see p. 288), though technically difficult, are sometimes a valuable diagnostic aid. A cuff of 2.5-cm. (1 inch) breadth is needed for accurate measurement (see p. 822). The balloon should also be long enough to encircle the arm, or decep-

tively high pressures will be recorded. The *auscultatory method* can often be used satisfactorily, provided the stethoscope head is small enough. Currently popular methods are the *palpatory method*, in which the systolic blood pressure is taken to be the point at which the pulse distal to the cuff becomes palpable in the course of deflation, and the *flush method*, in which the extremity is firmly compressed to render it relatively bloodless below the cuff followed by deflation of the

cuff with the systolic pressure recorded at the point flushing appears in the arm and hand below the cuff. Each has the disadvantage that the pulse pressure is not obtained and that the systolic reading is generally less than obtained by the auscultatory method.

In the **abdomen** the liver is usually palpable, sometimes as much as 2 or 3 cm. below the rib margin. Less commonly, the spleen and kidneys may be felt. Unusual masses should be investigated immediately by "flat film" of the abdomen, followed by intravenous pyelography and exploratory laparotomy if their innocent nature cannot be established. Urinary tract anomalies, renal embryoma, ovarian cysts and intestinal duplications are the commonest masses encountered. Abdominal distention at birth suggests meconium ileus. Later it suggests intestinal obstruction due to lower bowel obstruction or peritonitis. Scaphoid abdomen in the newborn suggests diaphragmatic hernia. At no period of life is the air content of the gastrointestinal tract so varied in amount, nor may it be so relatively great under normal circumstances. The abdominal wall is normally weak (especially in premature infants), and diastasis recti and umbilical hernias are common, particularly among Negro infants.

The **genitals** and **mammary glands** normally respond to transplacentally obtained maternal hormones, as described on page 291. The enlargement and secretion of the breasts in both sexes and the prominence of the female genitals, often with considerable nonpurulent secretion, are transitory manifestations requiring observation but no interference. The scrotum is relatively large; its size may be increased by the necessary trauma of breech delivery and also by a transitory hydrocele, which is easily distinguished from a hernia by palpation and transillumination. The testes may be in the scrotum or palpable in the canals, or may not be felt until spontaneous descent, which may not occur until later infancy. The male Negro infant usually has dark pigmentation of the scrotum before the rest of the skin assumes its permanent color.

The prepuce of the newborn infant is normally so tight and adherent that no information can be obtained as to later need for circumcision. Apparent hypospadias or epispadias should always arouse suspicion that the infant is actually a masculinized female with enlarged clitoris, since this may be the

first evidence of the adrenogenital syndrome (p. 1185). Erection of the penis is common and has no significance. Urine is usually passed during or immediately after birth; there may then normally follow a period as long as twenty-four hours without voiding.

Some passage of **meconium** usually occurs within the first twelve hours after birth, but may be delayed until the third or fourth day. Imperforate **anus** is not always visible, and may require the evidence obtained by the examiner's little finger or a rectal thermometer. Inexperienced physicians may mistake the dimple or irregularity of skin-fold often normally present in the sacrococcygeal midline for an actual or potential pilonidal sinus.

In examining the **extremities** the effects of fetal posture (p. 1250) should be noted if for no other reason than that their cause and usual transitoriness can be explained to the mother. The suspicion of a fracture or nerve injury associated with delivery is more commonly aroused by observing the extremities in spontaneous or stimulated activity than by any other means.

Certain **reflexes** are normally observed only in newborn infants. The *Moro reflex* is a startle reaction elicited by jarring the blanket or table on which the infant lies or by clapping the hands loudly near him. There are movements of abduction and adduction; the infant draws up the legs, brings forth the arms as in an embrace, and often begins to cry. The normal infant will show a symmetric response (Fig. 70). In the *tonic neck reflex* the infant assumes a fencing position when the head is turned sharply to either side; the arm and the leg on the side toward which the head is facing are extended and the others flexed (the resting infant in the upper photograph of Figure 70 shows the position). Both these reflexes are indicative of the immaturity of the nervous system of the newborn infant; they disappear after the first few months of life if the mental development of the infant progresses normally. A *grasp reflex* can be elicited in the hands and feet. If the palm of the hand is stimulated by the examiner's finger, the infant's fingers will grasp his finger and hold on firmly. If the sole of the foot is stroked from the heel forward, the toes turn downward.

*Chvostek's sign* and *Babinski's sign* can often be elicited in the newborn infant and at this age are merely another indication of the immaturity of the nervous system. The sucking reflex is active, but the infant lacks

FIG. 70. Moro reflex.

the voluntary buccal phase of swallowing and has only the involuntary pharyngeal and esophageal phases. The *patellar reflex* is present, but the response is variable, owing to difficulty in obtaining relaxation; its apparent absence does not necessarily indicate a pathologic condition. The *abdominal reflexes* are also difficult to elicit; their absence is not necessarily significant. The *corneal* and *pharyngeal reflexes* are active. The *cremasteric reflex* is usually present. The *rooting reflex* is described on page 118.

The pupillary *light reflex* is present, although the response is usually not sustained. The infant can see, but does not have coordinated vision. The sense of taste is present at birth. The infant is able to hear as soon

as the eustachian tube is aerated and the external auditory canal is free from debris. He usually reacts to loud noises by blinking, or may move his eyes or head toward the source of the noise. The infant responds to contact stimuli and cries from pain, exposure or discomfort. The lips are most sensitive to touch; when stimulated, the infant purses his lips and begins to suck. He winks, sneezes, yawns, coughs and hiccups. He can raise his head from the prone position. His grasp may be strong enough to support himself when holding the examiner's thumbs. When placed on his abdomen, he demonstrates suggestive crawling movements and, in water, swimming behavior. When he is held erect, reflex stepping movements are elicited.

## CARE OF THE NEWBORN INFANT

The basic requirements of the newborn infant are immediate assistance at birth, when needed, for the establishment of respiration and subsequent assistance in obtaining adequate nutrition, in maintaining a normal body temperature and in avoiding contact with infection. These requirements should be met in an environment which not only provides constant nursing and medical alertness for any sign of specific illness, but also reduces separation of the infant from his mother to a necessary minimum. The care of full term and premature infants differs only in the degree of emphasis on each of the three general factors. (See page 306.)

**Immediate Care at Delivery.** The infant should be suspended head downward immediately after delivery until the mouth, pharynx and nose have been cleared of fluid, mucus, blood and amniotic debris by gravity and gentle suction with a bulb syringe or soft rubber catheter. Wiping the palate and pharynx with gauze may lead to abrasions and the development of thrush, pterygoid ulcers (Bednar's apthae) or, rarely, to tooth bud infection with maxillary osteomyelitis and retrobulbar abscess formation. The infant should then be placed on his side, head downward, in a bassinet tilted at an angle of about 30 degrees to promote drainage from the respiratory tract for four to eight hours. With possible intracranial hemorrhage following difficult delivery the reverse position may be indicated. As a guide to prognosis and the need for particularly close observation or care in the delivery room and nursery, Apgar has devised a method of scoring which is of practical value (Table 53; Fig. 71). For reasons not clear, the stomachs of infants delivered by cesarean section may contain more fluid than those of infants delivered normally. It has been postulated that regurgitation and aspiration of this fluid may contribute to hyaline membrane disease (p. 324). It is recommended that the stomach be aspirated, preferably before the first breath is taken. If this theory is correct, it would be logical to remove any gastric contents in premature infants by suction, since they have a high incidence of hyaline membrane disease. An additional advantage to this procedure would be the immediate discovery of esophageal atresia if present.

**Resuscitation.** Failure to breathe spontaneously within one minute of birth is an indication for some method of resuscitation. If the central mechanism can be revived, the infant will usually be more effective in ventilating his lungs than will any available machine. When the need for resuscitation results from failure of peripheral rather than of central mechanisms, as in "previable" premature infants, most of whom demonstrate adequate initial function of the respiratory center, presently available resuscitative measures are notably ineffective.

Resuscitation should start with some method of simple, gentle physical stimulation such as snapping the soles of the feet with a finger or repeatedly passing a nasal catheter. The upper respiratory passage should be suctioned again and a small plastic or metal airway inserted to lift the tongue off the posterior pharyngeal wall. If the infant has an Apgar score of 1 or less, or if the pulse rate is less than 80 beats a minute, some method of artificial respiration or pulmonary inflation is usually indicated, since the lungs offer the most suitable surfaces for oxygenating the blood and reducing the carbon dioxide tension or concentration of any volatile anesthetics in the medulla. If a gentle flow of oxygen at pressures up to 25 cm. of water, administered either steadily or in puffs through a small mask, does not produce improved color and tone followed by spontaneous respiratory movements, direct laryngoscopy or direct intratracheal intubation with suctioning of the lower respiratory passages and an attempt to inflate the lungs through the application of short bursts of oxygen at higher pressures is indicated. The latter procedures should be carried out by personnel skilled in the techniques, of whom there should be one (usually the anesthetist) in every delivery room. Positive pressures much lower than 20 cm. of water are unlikely to introduce oxygen into the lungs. Pressures of 25 cm. of water may rupture the lung if only a small area is being expanded. On the other hand, positive pressures of 40 cm. of water have been safely applied by using a resuscitator which automatically limits the inspiratory phase to 0.1 second and provides an expiratory phase of 5.9 seconds. A recently proposed theory that capillary erection

Table 53. Evaluation of the Newborn Infant

Sign	0	1	2
Heart rate.....	Absent	Below 100	Over 100
Respiratory effort.....	Absent	Slow, irregular	Good, crying
Muscle tone.....	Limp	Some flexion of extremities	Active motion
Response to catheter in nostril (tested after oropharynx is clear)....	No response	Grimace	Cough or sneeze
Color.....	Blue, pale	Body pink, extremities blue	Completely pink

Sixty seconds after the complete birth of the infant (disregarding the cord and placenta) the 5 objective signs above are evaluated, and each is given a score of 0, 1 or 2. A total score of 10 indicates an infant in the best possible condition. (Modified from Virginia Apgar: Current Researches in Anesth. & Analg., 32:260, 1953.)

FIG. 71. Incidence and significance of Apgar scores (see Table 53) in newborn infants. (From data supplied by Dr. Virginia Apgar.)

is essential to initial alveolar expansion has not been confirmed by further experimental evidence, but its implications for presently used methods of resuscitation are of interest.

Several more elaborate devices for resuscitation are available. Among them are a "rocking-bed" type of respirator which rhythmically rocks the body so that the weight of the abdominal organs alternately presses against and falls away from the diaphragm, and the Bloxsum "air lock," which is an airtight tank incubator in which the pressure is rhythmically varied between 1.0 and 3.0 pounds per square inch above atmospheric pressure. The electrophrenic respirator of Sarnoff utilizes the infant's own musculature. Definite proof is lacking that any one of these devices is more effective than another, or that they are more effective than simple

physical stimulation plus the use of oxygen.

The elementary procedure of mouth-to-mouth breathing has presumably been successful in resuscitating some infants, but may well have been harmful to others by introducing infection or alveolar rupture from uncontrolled pressures. Even if safety devices are interposed, the gas thus supplied is less effective than oxygen. Manual compression of the soft thorax is unlikely to be followed by enough rebound expansion to produce air movement.

If the infant is making feeble but spontaneous respiratory movements, their effectiveness will be increased by raising the partial pressure of oxygen at the nose and mouth, even without any change in atmospheric pressure. Oxygen administration, particularly to premature infants, should always

be discontinued as soon as the baby can get along without it.

Warmth must be provided during any resuscitation requiring more than two or three minutes.

No drug advocated as a respiratory stimulant has proved to be of definite value; moreover, most of them may be convulsant if given in doses slightly greater than those supposed to stimulate breathing. For narcosis from maternally administered morphine derivatives, *n*-allyl normorphine (Nalline) in a dose of 2.1 mg. in 2 ml. of isotonic saline solution injected into the umbilical vein is indicated. This drug is a respiratory depressant and should not be used otherwise..

**Other measures.** The *umbilical cord*, after it has been cut and tied, requires no dressing. Initial and daily painting of the cord stump with a bactericidal dye while the infant is in the nursery results in a significant reduction in positive cultures for staphylococci from the nose and skin of newborns. Frozen sections of the cord at birth may expedite a diagnosis of neonatal sepsis through microscopic identification of perivascular leukocytic infiltrations. Likewise, the identification of a single umbilical artery through gross inspection of the cord at birth may lead to the early discovery of congenital anomalies.

The eyes of all infants must be protected against gonorrheal infection. Although numerous methods of ophthalmic prophylaxis with sulfonamide or antibiotic preparations have been advocated, the instillation of 1 per cent silver nitrate drops remains the best-proved and only universally lawful method. Prompt subsequent irrigation of the eyes with isotonic saline solution is said to reduce the incidence of chemical conjunctivitis without affecting the prophylactic efficacy.

Although hemorrhagic disease of the newborn (p. 336) may be due to factors other than vitamin K deficiency, the usual neonatal decrease in the plasma prothrombin level may be lessened by the intravenous administration of 10 mg. of vitamin K to the mother a few hours before delivery or by small doses to the infant immediately after birth. Since oral or intravenous administration is not always practical and since the duration of action of vitamin K, especially in the anoxic infant, is not known, an intramuscular injection of 2.5 mg. of a suitable preparation should be given in the delivery room and again on the third day of life to all infants. Larger amounts predispose to the development of hyperbilirubinemia and ker-

nicterus and should be avoided. Vitamin K<sub>1</sub> should be the preparation of choice, but is not at present available in a form suitable for intramuscular use.

**General Care. Nursery.** Routines for safeguarding the infant after he leaves the delivery room are modified by so many local circumstances that many important organizational and administrative aspects cannot be detailed in this brief section. Infants (1) born prematurely, (2) delivered operatively or with any unusual obstetric complication, (3) requiring resuscitation in the delivery room, (4) born to mothers with infections or premature rupture of the membranes, (5) born to toxemic or diabetic mothers, (6) born to mothers with a history of previous infants with death or serious illness during the newborn period, (7) with any important malformation or suspicion of such malformation, (8) under suspicion of blood incompatibility disease, or (9) delivered more than three weeks after expected confinement should be under close observation of the most interested and experienced nurses available and should be visited frequently by a physician until such time as complications of any of the foregoing circumstances may no longer reasonably be expected.

Infants not in the foregoing categories may be taken after examination in the delivery room to the "regular" newborn nursery, or may be placed in the mother's room if the hospital has a "rooming-in" arrangement.

The bassinet should be easily and frequently cleaned and preferably be of plastic material to allow easy visibility. All care should be given in the bassinet; this includes physical examination, change of clothing, temperature-taking, skin cleansing and other procedures which, if performed elsewhere, establish a common point of contact and thus provide a channel for cross infection. The clothing and bedding should be the minimum needed for the infant's comfort. Maintenance of a fairly constant temperature in the nursery at approximately 75° F. will simplify problems of clothing. The temperature of the infant may be taken by rectum or, if properly done, in the axilla. The interval depends on many circumstances, but need not be less than four hours during the first two or three days and eight hours thereafter. Axillary temperatures of 96° to 99° F. are considered within normal limits.

The *skin* requires little or no care beyond removal of blood and vernix from the face (largely for esthetic reasons) upon arrival in

the nursery. Clothing can be put on over the unbathed and unoiled body. Vernix is spontaneously shed within two to three days; much of it will adhere to the clothing, which should be completely changed daily. Daily baths with a soap or detergent containing hexachlorophene reduce the incidence of skin infection and should be instituted in any nursery where pustules are noted. As a permanent routine, bathing is probably not worth the nursing time required. The diaper should be checked before and after feeding and when the baby cries. When wet or soiled, it should be changed. Meconium or feces should be cleansed from the buttocks, and, if necessary, vernix from the body creases with sterile cotton moistened with sterile water. The foreskin of the male infant is normally tight and should not be retracted.

Little is gained by frequent *weighing* of the normal infant. A few accurate weights are of more use than numerous hurriedly taken ones. Weighing at birth and on alternate days thereafter is certainly sufficient, and even less frequent weighing is satisfactory for the majority of infants.

The problems of staphylococcal infections in the nursery are discussed on page 344.

**Feeding.** Only the initiation of feeding will be considered here (see p. 112 for other details). More mistakes are made by feeding the infant too much or too early than too little or too late. Both premature and term infants can, if necessary, tolerate a period as long as three days after birth without any

fluid intake. The one occasional but clear indication for prelacteal feeding is elevation of temperature not explained by other factors. Satisfactory progress is being made if the infant is no longer losing weight by the seventh day and gaining by the fourteenth. Many infants are unnecessarily fed artificially merely because the physician did not acquaint the mother with the delays normally encountered in establishing breast feeding.

If the principles of feeding are understood by the mother and the nursery staff, fixed routines for feeding will have little applicability. The schedule is less important than the principle of unhurried beginning and patient assistance and instruction by the nurse who takes the infant to the mother. But since some general plan may be useful from the standpoint of the hospital, the following is suggested: During the first twelve hours after birth no feeding is given. The infant is taken to the mother for his first feeding at 10 A.M. or 6 P.M., whichever is nearer the end of the twelve hour period of post-natal rest. Subsequent feedings are given every four hours day and night except for the first two nights, when no 2 A.M. feeding is given. Artificially fed infants should receive 5 per cent glucose in water for the first feeding, since regurgitation and aspiration of this solution are not likely to cause significant irritation of the respiratory tract. There is no clear need for complicating newborn care by the addition of any vitamins until the infant is at least two weeks of age.

## MULTIPLE PREGNANCIES

The reported incidence of twins varies; in general, it is highest among Negroes and East Indians, followed by whites of northern European extraction, and lowest among the Mongolian races. In the United States twins occur in approximately one of eighty-six pregnancies; other ratios are, Belgium, 1:56; United States Negroes, 1:70; United States whites, 1:88; Italy, 1:86; Greece, 1:130; Japan, 1:150; and China 1:300. Differences in the incidence of twins are due to differences in numbers of fraternal (polyovular) twins, the frequency of identical (monovular) twins being about the same in all racial and ethnic groups. It is roughly estimated that triplets occur in one of 86<sup>2</sup> pregnancies and quadruplets in one of 86<sup>3</sup> pregnancies

in the United States. Quintuplets and sextuplets are very rare, and it is questionable whether human septuplets have ever been born. The incidence of females increases with the number of fetal products of a multiple pregnancy, reaching approximately 53.5 per cent for quadruplets, as opposed to approximately 48.5 per cent among single births.

The occurrence of monovular twins appears to be independent of genetic or environmental influences. Such births constitute 25 to 33 per cent of twins. Polyovular pregnancies, on the other hand, are more frequent beyond the second pregnancy, in older women and in families with a history of polyovular twins. They may result from simultaneous maturation of multiple ovarian

ollicles, but follicles containing two ova have been described as a genetic trait leading to twin pregnancies. Monoovular twinning is believed to result from a retardation of growth in the early stages of development. When more than two fetuses coexist in the uterus, each may be derived from a separate ovum, all may come from the same ovum, or they may result from combined monoovular and polyovular twinning.

*Superfecundation*, the fertilization of an ovum by an insemination which takes place after one ovum has already been fertilized, has occasionally been advanced as the cause of differences in size and appearance of twins. *Superfetation*, the fertilization and subsequent development of an ovum when a fetus is already present in the uterus, has been proposed as a reason for differences in size of certain twins at birth, but objective evidence to support this theory is lacking. In fact, twins of unequal size at birth usually show the same degree of organ maturation.

Differentiation between monoovular and polyovular twins is usually made on the basis of the appearance of the placenta. An apparently single placenta may be present with either monoovular or polyovular twins. However, inspection of the polyovular placenta reveals for each fetus a separate chorion which crosses the placenta between the attachments of the cords. If the initiation of monoovular twinning occurs at the first cell division or during the morula stage, there may be two amnions and two chorions, and even two placentas, leading to an erroneous diagnosis of polyovular twins. For this reason, determination of whether twins of the same sex are monoovular or polyovular may have to be made on the basis of identical or non-identical physical characteristics. This is best done between the ages of two and four years, at which time differences caused by inequalities of intrauterine existence have been largely erased and differences created by external environmental factors have not yet become marked.

Physical criteria for determining monoovular twins are (1) that both be of the same sex; (2) that their features, including ears and teeth, be obviously alike (but they need not resemble one another more than the two lateral halves of one individual); (3) that their hair be identical in color, texture, natural curl and distribution; (4) that their eyes be of the same color and shade; (5) that their skin be of the same texture and color

(nevi may be differently apportioned and distributed); (6) that their hands and feet be of the same conformation and of similar size; (7) that their anthropometric values show close agreement; (8) that their finger, palm and sole prints be similar, the resemblance being either direct or mirror-imaged. Perhaps a more reliable method of determining zygosity of twins is through the use of detailed blood typing, including at least the ABO, Rh and MN systems. Monoovular twins should have identical blood types in all systems. Polyovular twins usually do not.

The identification of twins as monozygotic or dizygotic is of importance because the study of monozygotic twins is a useful scientific tool in determining the relative influence of heredity and environment on the etiology and course of many conditions.

One placenta may be markedly smaller than the other, or a dichorionic placenta may be divided disproportionately between the two fetuses. In either instance the fetus attached to the smaller placenta or smaller portion of placenta is usually smaller than its twin, or is malformed. With monoovular twins one umbilical cord may arise from the other after leaving the placenta. In such instances the twin attached to the secondary cord is usually malformed. Attachment of the cord to an inadequate portion of placenta or to the umbilical cord of the twin may also be responsible for fetal death, presumably as the result of an inadequate blood supply. Parabiosis of the placental circulations of monoovular twins, with arteriovenous shunts between the two circulations, may rarely result in the birth of twins, one of whom is large and polycythemic and the other small and anemic. Varying degrees of this condition may be responsible for apparent differences in size of monoovular twins.

Most twins are born prematurely, and maternal complications of pregnancy are more common than with single pregnancies. There is no significant difference between the neonatal mortalities of twin and single births in comparable weight groups. However, since most twins are premature by weight, their over-all mortality is higher than that of single births. The incidence of malformations incompatible with life is greater in multiple than in single pregnancies. In general, mortality rates of twins do not vary with order of birth if macerated fetuses are excluded. If one of the fetuses is macerated, the live twin is usually delivered first. Theoretically,

the second twin is more subject to anoxia than is the first because of the possibility that the placenta may separate after the birth of the first twin and before the birth of the second. For reasons which are not clear, premature infants born of multiple pregnancies appear to be more susceptible to retrolental fibroplasia than do premature infants born of single pregnancies. Notable differences in size at birth of monovular twins usually dis-

appear by the time the infants are six months of age.

*Conjoined twins* are probably the result of relatively late monovular twinning, as is the presence of two embryos in one amniotic sac. The latter condition has a high fatality rate, owing to obstruction of the circulation secondary to intertwining of the umbilical cords. The prognosis for conjoined twins depends on the possibility of surgical separation.

PERINATAL MORTALITY

The term "perinatal mortality" is applied to deaths of fetuses and infants weighing 1000 gm. or over which occur between twenty-eight weeks of gestational life and twenty-eight days of neonatal life. Emphasis on perinatal mortality, initiated by obstetricians, has been the greatest single factor in bringing about a team approach, involving obstetricians, pathologists, pediatricians, public health officials and nurses, to the problems of fetal and neonatal life. Table 54 illustrates the type of data obtained from studies of perinatal mortality, delineating the relative importance of principal causes of fetal and neonatal deaths. The reader will note that prematurity alone is not considered a cause of death, although the majority of fetal and neonatal deaths listed in the category "no abnormal state" occur among infants who are premature by weight at the time of delivery. It is also apparent that fetal and neonatal deaths contribute equally to perinatal mortality; the key position of the obstetrician in the reduction of perinatal mortality is obvious.

Table 54. Relative Importance of Causes of Fetal and Neonatal Deaths (Infants 1000 Gm. and Over)

Cause	Fetal	Neonatal	Total Perinatal
Anoxia*	25%	9%	34%
No abnormal state†	23%	9%	32%
Birth injury	2%	8%	10%
Malformations	4%	5%	9%
Abnormal pulmonary ventilation‡	0%	7%	7%
Infection	1%	4.5%	5.5%
Erythroblastosis	0.6%	1.1%	1.7%
Other	0.7%	0.1%	0.8%
Total	56.3%	43.7%	100.0%

Adapted from R. E. L. Nesbitt, Jr., and G. W. Anderson: Perinatal Mortality: Clinical and Pathologic Aspects. Obst. & Gynec., 8:50, 1956.

\* Defined as any interference in the supply of oxygen from mother to fetus producing visible structural changes in the fetus or infant at autopsy.

† Defined as lack of adequate lethal factors demonstrable at autopsy to explain the death.

‡ This category includes so-called pulmonary hyaline membrane disease.

PREMATURITY

**Definition.** A premature infant is a live-born\* infant weighing 2500 gm. (5 pounds 8 ounces) or less at birth. This definition, although in common use, is admittedly un-

\* Live birth is defined by the World Health Assembly (1950) as "the complete expulsion or extraction from its mother of a product of conception . . . which, after such separation, breathes or shows any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of the voluntary muscles, whether or not the umbilical cord has been cut or the placenta is attached." This definition is approved by the American Public Health Association.

satisfactory, since it includes infants of low birth weight resulting from factors other than prematurity and excludes those actually premature who would have been of large size if carried to term. The additional qualification of a crown-heel length of 47 cm. (18½ inches) or less has been little used. The prognosis for survival of premature infants (less than thirty-seven weeks' gestation) in any weight group is directly related to gestational age. For example, in one analysis the neonatal mortality of a group of seventy-nine infants between 1000 and 1499 gm. birth weight

was 46 per cent; when the group was divided by recorded gestational age, the infants of less than thirty weeks had a mortality rate of 63 per cent, compared to 21 per cent for those in the same weight range, but with gestational ages of thirty-four to thirty-seven weeks (Steiner and Pomerance).

**Mortality and Incidence of Prematurity.** About two thirds of all mortality among newborn infants occurs in the relatively small percentage born prematurely (see Table 55). In a few instances no cause of death other than prematurity can be demonstrated; in the majority the cause of death, such as infection or hemorrhage, can be identified if careful postmortem study is made. From Figure 68 (p. 286) it is apparent that the mortality for both premature and term infants follows the same numerical relationship on successive days after birth, so that the basic problem of the premature, like that of the term infant, is to survive the first few days.

Table 55 presents the approximate distribution of live-born premature infants in the United States in 1950 by birth weight and the mortality rate for each group in comparison with those from a hospital which devotes special attention to research in problems of newborn infants, in order to emphasize that such attention does result in lowering of neonatal mortality rates. It is also apparent how greatly deferment of premature birth could affect absolute mortality.

Since nonwhite infants tend to weigh less at birth than white infants of the same gestational age, the incidence of prematurity based on a birth weight of 2500 gm. or less is greater among nonwhite infants, but the expected mortality rate is lower.

In the United States the incidence of premature birth is approximately 7 per cent of all live births in population groups of reasonably favorable socio-economic circumstances, although rates from 6 to 16 per cent are reported from various sections.

**Causes of Prematurity.** The cause of premature birth is not known in most instances. The relationship between multiple pregnancy and prematurity is clear. Maternal toxemia and infections increase the likelihood of premature delivery; congenital syphilis was formerly a frequent cause. In some instances premature labor may be initiated or its induction may be required because of factors such as placenta previa, premature separation of the placenta, toxemia, diabetes mellitus or severe sensitization to the Rh blood factor. Premature rupture of the membranes and

other obstetric disturbances may be considered manifestations of premature delivery almost as properly as causes. Chronic maternal malnutrition is undoubtedly an important factor in premature birth. Malnutrition tends to be associated with poor general hygiene, fatigue, increased frequency of infection, inadequate prenatal care, and other factors which contribute to increased fetal and neonatal loss. However, the majority of premature births are not satisfactorily explained.

**Prevention.** The higher the rate of premature births in any locality, the more obvious should be the steps which could result in its reduction. Usually these are in the areas of health education and better medical services. Preliminary studies suggest that "relaxin," an extract from the ovaries of pregnant sows, may have some value in the prevention of premature labor.

**Pathology.** Neonatal deaths among premature and term infants result from the same general group of pathologic disturbances (Table 54), the principal differences being in the distribution of the causes of death. When the cause of death is sought by careful macroscopic and microscopic postmortem examination, it is found in a high percentage of instances. Prematurity itself should not be considered a cause of death in an infant born alive. The principal causes of death among premature as well as term infants are anoxia,

**Table 55. Approximate or Predictable Average Distribution of 100 Live-Born Premature Infants on the Basis of Birth Weight and Approximate Expected Mortality Rate for Each Weight Group**

<i>Birth Weight</i>	<i>Percentage and Number of Infants</i>	<i>Approximate Mortality Rate (U.S. Average)*</i>	<i>Approximate Mortality Rate (Research Hospital)†</i>
1000 gm. or less . . . . .	6	87%	90%
1001-1500 gm. . . . .	8	55%	40%
1501-2000 gm. . . . .	19	21%	11%
2001-2500 gm. . . . .	67	5%	4%
All under 2500 gm. . . . .	100	17%	14%
All over 2500 gm. . . . .	100	0.8%	0.4%

† Boston Lying-In Hospital.

birth injuries (principally cerebral), malformations, pulmonary "hyaline membrane syndrome," bronchopneumonia, septicemia and other infections.

*Pulmonary hyaline membranes* associated with "resorption atelectasis" are found at autopsy in approximately 50 per cent of premature infants dying one hour to four days after birth and are seen with any frequency in full term infants only in those born by cesarean section or of diabetic mothers.

*Hemorrhage*, whether associated with trauma, anoxia, infection, or defect of clotting mechanism, is frequent and often severe. Subcutaneous ecchymoses, bleeding into the choroid plexus, subependymal and intraventricular hemorrhages are all frequently found in premature infants and are presumably due to "increased capillary fragility." Sudden shock and collapse during the first few days of life are usually due to intraventricular hemorrhage. Fatal hemorrhage into the lungs may also occur without clear cause.

*Retrolental fibroplasia* (see p. 1343) is a retinopathy of premature infants which results from too great an exposure to atmospheres with increased oxygen content. Before this effect of oxygen administration was appreciated partial or complete blindness was reported in 5 to 25 per cent of surviving infants whose birth weights were below 4 pounds (1800 gm.); the condition had replaced gonococcal ophthalmia as the commonest cause of blindness in children. Adoption of the practice of administering oxygen only in such amounts and at such times as are absolutely necessary for respiratory distress has practically eradicated the disease.

*Kernicterus* associated with hyperbilirubinemia (see p. 1077) is seen in 2 to 20 per cent of autopsies of premature infants. Incidences of kernicterus approaching the latter figure are probably the result of procedures used locally in the care of premature infants, such as administration of large amounts of vitamin K analogues to mothers in labor or to newborn infants, and use of sulfisoxazole as chemoprophylaxis (see p. 334).

**Care.** At birth the same measures for clearing of airway, initiation of breathing, care of the cord and of the eyes are required as for full term infants. The next considerations are (1) need for incubator care, (2) need for increased oxygen, and (3) details of feeding. Safeguards against infection and against careless or inefficient nursing can never be relaxed. Finally, the need of instructing the mother for the care at home

and the question of prognosis for later growth and development require special consideration.

**Incubator Care.** The original purpose of the incubator was the efficient conservation of body heat; to this have been added regulated humidity and oxygen supply and reduced atmospheric contamination. No rigid rule can be used to decide which premature infants should have incubator care, but, in general, the smaller the infant, the more helpful is such care. Many relatively large premature infants can be maintained satisfactorily in bassinets in a room of suitable temperature. On the other hand, for some term infants presenting special problems, incubator care is advantageous. The incubator is best prewarmed to 85° F. for infants above 3½ pounds, and to 90° F. or more for smaller infants. If the infant's temperature taken thirty minutes after placement in the incubator has risen by more than 2 degrees and/or reached 98° F., the temperature of the incubator may be slightly reduced. Simultaneous recordings of infant and incubator temperatures at thirty minute intervals for a few hours will usually be adequate for adjustment to a routine of four-hourly temperature readings. Stability of the infant's temperature should be obtained rather than any exact temperature level. A temperature varying in a range of 2 degrees, the low point of which is 94° F. (axillary) is probably more satisfactory than one which oscillates in a wider range about a mean of 98.6° F. If the infant is weakened, as by trauma or infection, the aim should be to keep his temperature somewhat nearer the 98° F. mean; such infants do not stabilize well at any temperature.

Though constancy of relative humidity within the incubator is, in general, more important than any fixed level, a relative humidity of 60 per cent or higher is more desirable than a lower one. If an incubator is not available, the general conditions of temperature and humidity control can be attained by the intelligent use of blankets and warm water bottles and by control of the temperature and humidity of the room. The infant should be removed from the incubator only when the gradual change to the atmosphere of the nursery is not accompanied by a significant change of his temperature, color or activity. The removal may be only a day or two after birth for some infants, or at more than a month of age for other and less mature ones.

Since disturbed pulmonary ventilation is responsible for a large portion of the deaths

of premature infants, it seems logical to increase atmospheric oxygen during the first hours or days following birth when there are such definite indications as cyanosis or dyspnea. Owing to the risk of retrolental fibroplasia, its use as a general measure should be avoided. When oxygen is administered in a closed incubator, its atmospheric concentration should be kept at the lowest level providing adequate relief for the infant, and administration of it should be discontinued just as soon as possible. The irritant action of oxygen is greater in a dry than in a humid atmosphere, so that administration of it is an additional reason for maintaining the relative humidity at 60 per cent or higher. Supersaturation of the atmosphere of the incubator to create a mist reduces insensible water loss from the lungs, but it has not been shown to affect the prognosis of the infant, nor has the addition of surface-tension-reducing agents to the nebulized water.

**Feeding.** There are a variety of techniques for the feeding of premature infants. There is general agreement on the importance of avoiding fatigue and the aspiration of food as fed or by regurgitation. No one method of feeding will avoid these risks unless the person using it has been well trained in the process. Large premature infants can often be fed by bottle or at breast. Since the effort of sucking is usually the limiting factor, breast feeding is least likely to be successful. In bottle feeding, effort may be reduced by use of special small, soft nipples with large holes or standard nipples with large holes boiled until soft. Infants as small as 3 pounds at birth are occasionally vigorous enough for bottle feedings. Smaller or less vigorous premature infants should be fed by gavage; a soft plastic tube of no. 5 French external and approximately 0.05 cm. internal diameters with a rounded atraumatic tip and two holes on alternate sides is preferable. The tube is passed through the nose until approximately 1 inch of the lower end should be in the stomach. The free end of the tube is then placed under water. If bubbles appear with each expiration, the catheter is in the trachea and must be reinserted into the proper position. The free end of the tube has an adapter into which the tip of a glass syringe is fitted, and the measured amount of feeding is allowed to flow in by gravity. Such tubes may be left in place for three to seven days before replacement by a similar tube through the alternate nostril. The tubes may be cleaned, sterilized, and reused, but are usually dis-

carded after one use. An occasional infant has enough local irritation from an indwelling tube that troublesome secretions gather around it in the nasopharynx. In such instances a sterile no. 10 French catheter may be passed through the mouth by a skilled person and removed at the end of each feeding. Change to bottle or breast feeding may be instituted gradually as soon as the infant displays general vigor adequate for oral feeding without fatigue. The so-called Breck feeder, with which food is forced into the infant's mouth, is unsafe in any hands. Premature infants can be fed successfully and safely with a rubber-tipped medicine dropper by a nurse skilled in the procedure.

The comparative inactivity of premature infants, their low heat production, if heat is artificially conserved, and, perhaps, their relatively large body water content at birth, all reduce the immediate need for calories, water and electrolytes. Nothing seems to be gained by giving food during the first twenty-four hours after birth, and much may be lost if aspiration or undue fatigue occurs. The smaller and less active infants may be safely allowed at least two days without intake. The first feedings should be sterile 5 or 10 per cent solutions of glucose in water. The interval between them is generally somewhat shorter for smaller infants, and may be even less than two hours when feeding is by an indwelling tube. Experience and observation of the individual infant best determine intervals and amounts, but some such routines as those in Table 56 are suitable for most infants. The main principle should be to proceed more gradually the smaller the infant, but never to hurry with any.

After the eighth feeding, as indicated in Table 56, increases can be made daily with not more than 4 cc. added to each of the eight daily feedings (32 cc. per day) for the smaller infants or 8 cc. to each of the six feedings (48 cc. per day) for the larger ones. By the time the infant is a week of age he should be receiving approximately 40 to 50 calories per pound (90 to 110 per kilogram), and by two weeks, 50 to 60 calories (110 to 130 per kilogram).

Some physicians prefer mixtures of partly skimmed cow's milk, water and carbohydrate for feeding premature infants (see p. 124). As shown in Table 57, such mixtures provide more protein and carbohydrate and less fat than does human milk; the intake of minerals is about threefold. The proponents of human milk contend that calories lost as fecal fat

‡ H. H. Gordon, S. Z. Levine, and H. McNamara: Feeding of Premature Infants. A Comparison of Human and Cow's Milk. Am. J. Dis. Child., Vol. 73.

may be compensated by slightly increasing the total feeding; moreover, investigations have shown higher retentions of the fat of human milk than that of cow's milk. The increased retention of nitrogen with cow's milk mixtures has not been demonstrated to be of critical importance. The excess mineral content of cow's milk requires removal by the

kidney; whether this constitutes a "load" of clinical importance is not known.

Within the limits mentioned above, there is no clinical evidence to indicate that the composition of the food is a significant factor for survival or subsequent growth.

There is need for an increased intake of vitamins C and D. Intermediary metabolism

of phenylalanine and tyrosine is incomplete unless ascorbic acid is provided. Moreover, any tendency to loss of fecal fat involves loss of fat-soluble vitamins and calcium. Approximately 50 mg. of ascorbic acid and 1000 I.U. of vitamin D daily begun during the second and third weeks, respectively, appear to be ample. It has not been shown that supplementation with any other vitamins is necessary. The addition of iron to the diet is discussed on page 932.

Application of the foregoing general principles of nutrition will generally result in satisfactory rates of growth, but individual differences are to be expected. Therefore the needs of the individual infant should be followed, and the usual caloric recommendations after the second week of life are to be applied only as an approximation. Certain infants with small gastric capacities may require caloric concentrations as high as 30 per ounce in order to gain weight satisfactorily.

The properly fed premature infant may have from one to six stools of semisolid consistency daily; sudden increase in number is more reason for alarm than any arbitrarily stated frequency. He should not vomit or regurgitate. He should be satisfied and relaxed after a feeding, but may normally show the activity of hunger shortly before the next one. All these signs are more important than his rate of gain in weight.

**Prevention of Infection.** Prevention is accomplished by safeguarding the infant's food and the few objects which come in contact with him, reducing his direct and indirect contacts with nursery personnel (including other infants) and preventing contamination of the air he breathes. No one should enter the nursery unless his presence is essential, and no adult with an infection has a responsibility toward a premature nursery as essential as staying out of it. Gowns, caps, masks and hand scrubbing techniques do not guarantee safety of the infants if an infected person enters the nursery.

Prevention of transmission of infection from infant to infant is difficult because clinical evidence of infection is infrequently clearly manifest by either term or premature newborn infants. If the unit admits infants born outside the hospital, it should be assumed that they are infected until a week or more of observation in a special nursery or an incubator with an individual air supply proves otherwise. If the only admissions are infants born in the hospital, the possibility

that one will introduce infection is greatly reduced, provided careful attention is given to the obstetric history.

Perhaps the most important factor in the successful care of premature infants is the skill, experience and number of the *nursing* staff. It is as much the responsibility of the physician to insist upon expert nursing as upon the details of care.

**General Considerations of Disease.** Prematurity tends to increase the severity and to reduce the clinical manifestations of all neonatal diseases. Subcutaneous and intracranial hemorrhage, "primary" atelectasis, hyaline membrane syndrome, pneumonia, bacteremia and hyperbilirubinemia occur more frequently among premature than among term infants. Retrolental fibroplasia is seen almost exclusively in premature infants.

**Drugs.** Renal clearances for almost all substances excreted in the urine are diminished in all newborn infants, and perhaps more so in prematures. One half or less of the customary dose of any drug excreted chiefly by the kidney is usually adequate to maintain a therapeutic level, when given at longer than the customary interval between doses. For instance, highly satisfactory levels of penicillin and streptomycin are maintained on doses given at twelve-hour intervals. Drugs detoxified in the liver or requiring chemical conjugation before renal excretion should also be given with caution and in smaller than usual doses. Intramuscularly administered broad-spectrum antibiotics are absorbed less well

FIG. 72. Grid for recording weights of premature infants. The average weight increments are indicated on the basis of weight at birth. (J. Dancis et al.: *J. Pediat.*, Vol. 33.)

Table 58. Estimated Developmental Ratings Achieved by 370 Infants Less than 1250 Gm. in Birth Weight\*

Rating	Number so Rated (1 to 28 Years after Birth)	
	Physical Development	Mental Development
Normal, average or above . . .	200	264
Slight deviation from expecta- tion for age . . . . .	116	68
Poor . . . . .	36	23
Bad . . . . .	13	6
Extremely subnormal . . . . .	5	9

\* Arranged from data of Hess: Pediatrics, Vol. 11.

than penicillin and streptomycin, presumably owing to the severity of local tissue reaction and to relative circulatory inadequacy. Broad-spectrum antibiotics are also poorly absorbed from the intestinal tract unless administered in dilute form, again presumably because of local irritant effects. Decision as to the administration of antibacterial agents to possibly infected infants should be made on an individual rather than on a routine basis, owing to the dangers of (1) development of infections with organisms resistant to antibacterial agents, (2) destruction or inhibition of intestinal bacteria which manufacture significant amounts of essential vitamins (e.g., vitamin K and thiamine) and (3) possible deleterious interference in important metabolic processes (e.g., the role of sulfisoxazole in hyperbilirubinemia).

Since pure food and drug laws and regulations are based on toxicity studies on adult animals and human beings, apparently "safe" drugs may not be so for newborn infants, especially premature ones. Oxygen, vitamin K analogues and sulfisoxazole (Gantrisin), all presumably "safe" drugs, have proved to be toxic to newborn premature infants in amounts not harmful to term infants. Thus administration of any drug to newborn infants, particularly in large doses, should be done with care and never as a "routine."

Gamma globulin levels of premature infants at birth are significantly lower than those of their mothers at the time of delivery or than those of term infants; since they undergo the usual "physiologic" decrease during the first months of life, the routine administration of gamma globulin on discharge from the hospital has been advocated as a

prophylactic measure. As yet no adequate evaluation of this procedure is available.

**Prognosis.** (See p. 306 for mortality rate within first few weeks of life.) Recent evidence indicates that the mortality of premature infants who survive to be discharged from the hospital is approximately three times that of full term infants during the first two years of life. Most of these deaths are attributable to infection and are, therefore, at least theoretically preventable.

Data in regard to attainments in growth and development are inadequate to permit more than general deductions. Physical growth usually tends to overtake that of term infants during the second year; this occurs earlier in premature infants of larger size at birth and tends to be later in the more premature, among whom a few remain small throughout childhood (see Table 58). Premature birth in itself may prejudice later development, and there is also a greater frequency of other obstetric factors, such as intrauterine anoxia and intracranial hemorrhage, than would occur in infants born at term.

A high incidence (50 per cent) of refractive errors presumably unconnected with retrolental fibroplasia has been reported by Howard and Worrell in twenty-two children of birth weight below 4 pounds (1820 gm.) examined at ages of eight to nineteen years.

Behavior and personality problems also appear to be common in children born prematurely. The circumstances of nursery care in early infancy and of home care thereafter conspire against a normal relationship between the prematurely born infant and his family. The extent to which natural parental anxiety and overprotectiveness may foster an abnormal emotional environment for the growing infant should be greatly reduced by avoiding unnecessarily prolonged hospitalization and by painstaking education of the families.

**Home Care.** While the infant is in the hospital the mother should be instructed for her responsibilities when the baby is discharged. This program will include at least one visit to her home by a person capable of evaluating domestic arrangements and of advising as to improvements, if needed. Premature infants are usually sent home when they reach 5½ pounds (2500 gm.) in weight, but many may go before that time, while others should be kept longer.

# POSTMATURITY AND PLACENTAL DYSFUNCTION

Postmaturity is defined as a gestation exceeding the normal by seven to twenty days or more. Large size of the infant does not correlate well with late delivery, but does tend to correlate with large size of either parent, multigravidity, and diabetes or the prediabetic state in the mother and possibly also in the father.

Often associated and frequently confused with postmaturity is a syndrome termed *placental dysfunction syndrome*.

## POSTMATURITY

**Incidence and Etiology.** The incidence of postmaturity varies with its definition and with local obstetric practices. Approximately 25 per cent of all pregnancies end on or after the 287th day of gestation, 12 per cent on or after the 294th day, and 5 per cent on or after the 301st day. The etiology of postmaturity will presumably remain unknown until the mechanism of onset of labor is fully understood.

**Clinical Manifestations.** The appearance and behavior of the postmature infant approximate those of an infant one to three weeks of age. He tends to have absence of lanugo, long nails, abundance of scalp hair, white skin and an increased alertness. The skin may be parchment-like with desquamation, which is the result of gradual but progressive diminution of vernix caseosa beyond term.

**Prognosis.** When postmaturity exceeds three or more weeks, there is a significant increase in mortality, which in some series has approximated three times that of a control group of infants born at term; the fetal mortality exceeds that of the neonatal period. Each has been lowered markedly through improved obstetric management. Primiparity and maternal age over twenty-five years appear to increase the mortality rates.

**Treatment.** The induction of labor before the cervix is soft and dilated is felt by most obstetricians to be a greater risk than is postmaturity itself. A possible exception is the performance of cesarean section on elderly primigravidas who go more than a week or two beyond term, particularly if there is any evidence of fetal distress.

## PLACENTAL DYSFUNCTION SYNDROME

**Incidence and Etiology.** The incidence of some clinically recognizable form of placental dysfunction is said by Clifford to be as high as 12 per cent of all births. The incidence of the clearly recognizable form of the syndrome, with yellow staining of the vernix and skin, is approximately 1.2 per cent of all births. *Only about 20 per cent of infants with placental dysfunction syndrome are postmature.* Premature infants and infants of toxemic mothers, elderly primigravidas and women with "reproductive inefficiency" often associated with small or poorly attached placentas account for the major portion of the remainder. It has been postulated that this syndrome is the result of degenerative changes in the placenta resulting in progressive reduction of oxygen and nourishment for the fetus.

**Clinical Manifestations.** Clifford divides infants with the placental dysfunction syndrome into three groups, assuming that they are postmature (see above): *stage I*—infants

FIG. 73. Placental dysfunction syndrome, stage III. Note long, thin infant with loose, peeling, parchment-like skin, alert expression, staining of skin and nails. (From Clifford: *Advances in Pediatrics*, Vol. 9. Yearbook Publishers, Inc.)

with the usual signs of postmaturity, which are desquamation, long nails, abundant hair, white skin and alert facies and loose skin, especially around the thighs and buttocks, giving the appearance of recent loss of weight; *stage II*—infants with the changes of stage I plus meconium-stained amniotic fluid, skin, vernix, umbilical cord and placental membranes, possibly a manifestation of fetal anoxia; *stage III* (Fig. 73)—infants with the signs of stages I and II, except that their nails and skin are stained a bright yellow and the umbilical cord yellow-green.

**Prognosis.** Stage I infants have no known mortality associated with the syndrome, although up to one third of them have been reported as showing some evidence of respiratory distress or central nervous system irrita-

tion. Stage II infants are born at the height of intrauterine anoxia. About two thirds of them have severe respiratory symptoms, apparently resulting from the aspiration of meconium-containing amniotic fluid. A smaller number have clinical signs of anoxic cerebral damage. The over-all mortality is estimated to be about 35 per cent. Live-born stage III infants have presumably survived the acute anoxic phase of stage II; they have the same clinical problems, but with a lower morbidity, and a mortality of approximately 15 per cent.

**Treatment.** The treatment of placental dysfunction lies chiefly in preventing the conditions which predispose to it. It therefore constitutes an obstetric and perhaps a genetic and social problem. Aspiration pneumonia and cerebral anoxia are treated symptomatically.

## DISEASES OF THE NEWBORN INFANT: FULL TERM AND PREMATURE

### CONGENITAL ANOMALIES

Congenital anomalies are important as a cause of stillbirths and of neonatal deaths, but are perhaps even more important as causes of physical defects and of metabolic disorders. Anomalies are discussed in general on page 243 and specifically in the sections on the various systems of the body. For congenital mental defects, see page 1129, and for congenital metabolic and chemical disorders, see page 250.

Recognition of anomalies as early as pos-

sible is desirable. For some, such as tracheoesophageal fistula or intestinal obstruction, immediate medical and surgical therapy is mandatory for survival. For others, such as stenosis of the posterior nares, early treatment will avoid subsequent difficulties. Furthermore, early diagnosis permits a planned approach to parents, who are likely to be assailed by anxiety and guilt when they become aware of the existence of a congenital anomaly.

### CLINICAL MANIFESTATIONS OF DISEASE DURING THE NEWBORN PERIOD

Recognition of disease in the newborn infant is dependent upon knowledge and appraisal of the significance of a limited number of relatively nonspecific clinical signs and symptoms.

*Cyanosis* usually indicates respiratory insufficiency which may be due to pulmonary conditions or secondary to intracranial hemorrhage. If it is due to the former, respirations tend to be rapid and may be accompanied by thoracic cage retraction of varying degrees. If it is due to the latter, respirations tend to be irregular and weak and often slow. Cyanosis

persisting for several days, when unaccompanied by obvious signs of respiratory difficulty, is suggestive of cyanotic congenital heart disease or methemoglobinemia. Episodes of cyanosis may be the presenting sign of bacteremia or meningitis.

*Convulsions* usually point to the central nervous system and suggest intracranial hemorrhage, cerebral anomaly, subdural effusion, meningitis, tetany or, rarely, pyridoxine dependency or hypoglycemia. They may also be the first sign of bacteremia or other severe infection and are often seen as a nonspecific

sign in any severe illness. Rapid or striking changes in serum electrolyte concentrations may also cause convulsions, as may "withdrawal changes" in infants of mothers addicted to narcotics.

*Lethargy* is seen in the anoxic infant, in the infant with cerebral defect, either congenital or acquired, in the infant with severe infection, and, indeed, in the presence of almost any severe disease. Lethargy appearing after the second day should in particular suggest infection.

*Irritability* may be a sign of discomfort accompanying intra-abdominal conditions, meningeal irritation, infections, or any condition producing pain. Toward the latter part of the newborn period, as in later infancy, the ear drums should always be examined as a possible source of pain.

*Failure to feed well* is seen in most sick newborn infants and should always occasion a careful search for possible abnormalities.

*Fever* may be the result of too high an environmental temperature due to hot weather, overheated nurseries or incubators, or too many clothes or bedclothes. It is also seen in "dehydration fever" of newborns. If the preceding causes of fever can be eliminated, serious infection (pneumonia, bacteremia, meningitis) must be ruled out. On the other hand, serious infections often occur without provoking any febrile response in newborn infants.

*Jaundice during the first twenty-four hours of life* should be considered due to erythroblastosis fetalis until proved otherwise. Cytomegalic inclusion disease and toxoplasmosis should also be considered.

*Jaundice after the first twenty-four hours*

may be "physiologic," due to septicemia, hemolytic anemia, galactosemia, cytomegalic inclusion disease, hepatitis, congenital atresia of the bile ducts, inspissated bile syndrome following erythroblastosis fetalis, syphilis or toxoplasmosis.

*Vomiting* during the first day of life suggests intestinal obstruction or increased intracranial pressure. Anteroposterior and lateral *upright* films of the abdomen are indicated, followed by barium studies if the diagnosis remains in doubt. Later, although it still points to the central nervous system or gastrointestinal tract, vomiting may be a non-specific symptom of an illness such as septicemia. It is also seen as a common manifestation of overfeeding, pyloric stenosis, milk allergy, duodenal ulcer, adrenal insufficiency and a reflection of a "nervous" or apprehensive mother, or of an actual emotional upset in the parents. Infants placed in body casts for orthopedic treatment often vomit transiently, apparently as a manifestation of frustration of physical movement. Vomitus containing dark blood is usually a sign of terminal illness, whatever the cause.

*Diarrhea* may be a symptom of overfeeding, acute gastroenteritis or a nonspecific symptom of infection (*parenteral diarrhea*). It may be seen in conditions accompanied by compromised circulation of part of the intestinal or genital tract such as strangulated hernia, intussusception, and torsion of the ovary or testis.

*Failure to move an extremity* or part of an extremity suggests fracture, dislocation or nerve injury. It is also seen in osteomyelitis and other infections which cause pain on movement of the affected part.

## DISTURBANCES RELATED TO INTRAUTERINE CONDITIONS OR TO DELIVERY

### BIRTH INJURY

The term *birth injury* is used to denote not only avoidable and unavoidable trauma incurred by the infant at the time of birth, but also permanent damage occurring during or shortly after birth, particularly to the central nervous system. Most lay persons interpret *birth injury* as meaning avoidable trauma incurred through lack of medical skill or attention. In order to prevent later misunderstandings, recriminations and self-recriminations on the part of parents of a child who has

residuals from birth trauma, anoxia or disease, it is important that the physician take time to inform them about the broad use of the term "birth injury" and the fact that trauma or anoxia may, in our present state of obstetrical knowledge and skill, be unavoidable during the process of birth.

### HEAD

*Caput succedaneum* is a diffuse, edematous swelling of the soft tissues of the scalp involving the portion presenting during delivery. General or localized ecchymotic discolor-

FIG. 74. Cephalhematoma of the right parietal bone.

oration may be present. The edema disappears within the first few days of life. Analogous swelling, discoloration and distortion of the face are seen in face presentations.

*Molding* of the head and overriding of the parietal bones are frequently associated with caput succedaneum and become more evident after the caput has receded, but disappear during the first weeks of life.

*Erythema, abrasions, ecchymoses and subcutaneous fat necrosis* (p. 1278) may be seen after forceps deliveries. Their location depends upon the area of application of the forceps. Ecchymoses may be seen after manipulative deliveries and occasionally in premature infants for no discernible reason.

*Subconjunctival hemorrhages* are frequent, and *petechiae* of the skin of head and neck are not uncommon. Both are probably secondary to a sudden increase in intrathoracic pressure during passage of the chest through the birth canal. Parents should be assured that they are temporary and the result of normal hazards of delivery.

*Cephalhematoma* (Fig. 74) is a subperiosteal hemorrhage, hence always limited to the surface of one cranial bone. Other points of distinction from caput succedaneum are that there is no discoloration of the overlying scalp due to subcutaneous hemorrhage and that visible swelling usually is not present for several hours after birth, since subperiosteal bleeding is a slow process. In approximately 25 per cent of cephalhematomas there is an underlying skull fracture. It is rarely of the depressed type, although a sensation of central depression suggesting underlying fracture or bony defect is usually encountered on palpation of the rim of a cephalhematoma. Cranial meningocele may be differentiated

from cephalhematoma by pulsation, increased pressure on crying and the roentgenographic evidence of bony defect. Cephalhematomas begin to calcify by the end of the second week. Most are resorbed during the first six weeks of life.

A few remain as bony protuberances for years, however, detectable roentgenographically as widening of the diploic space; cyst-like defects may persist for months or years. Despite these residuals, cephalhematomas require no treatment. Since the introduction of infection, especially with antibiotic-resistant staphylococci, is the only serious complication, incision or aspiration accompanied by antibacterial therapy is contraindicated.

*Fractures of the skull* may occur as a result of pressure from forceps or against the maternal symphysis pubis, sacral promontory or ischial spines. Linear fractures are the most common. They cause no symptoms and require no treatment. Depressed fractures are usually indentations of the calvarium similar to a dent in a Ping-pong ball. It is advisable to elevate such depressions surgically to prevent cortical injury from sustained pressure. Fracture of the occipital bone with separation of the basal and squamous portions almost invariably causes fatal hemorrhage, owing to disruption of the underlying sinuses. It ordinarily results from traction on the hyperextended spine of the infant with the head fixed in the maternal pelvis during breech deliveries. It is rarely seen with skilled obstetric techniques.

#### INTRACRANIAL HEMORRHAGE

Intracranial hemorrhage may result from trauma or anoxia and, rarely, from a primary hemorrhagic disturbance or congenital vascular anomaly. Traumatic hemorrhage is especially likely when the fetal head is large in proportion to the size of the mother's pelvic outlet; when for other reasons the labor is prolonged; in breech deliveries; in precipitate deliveries; or when there is injudicious mechanical interference with delivery. On the other hand, the proper use of forceps is thought to decrease the incidence of intracranial bleeding in prolonged, hard labors. Intracranial hemorrhage may occur in infants, especially prematures, delivered spontaneously without apparent trauma. In premature infants subependymal, subarachnoid, intracerebral and intraventricular hemorrhages are common (Fig. 75). Spontaneous intraventricular hemorrhage in which no physical damage to the tentorium, falx or

other structures is found at autopsy is practically limited to premature infants. Conversely, massive subdural hemorrhages, often associated with tears in the tentorium cerebelli or less frequently in the falx cerebri, are encountered more often in full term than in premature infants. Hemorrhage due to anoxia tends to be petechial, and subarachnoid and intracerebral in distribution. There is usually only mild extravasation of erythrocytes, and symptoms and sequelae are dependent more on anoxia than on hemorrhage. Primary hemorrhagic disturbances usually give rise to subarachnoid hemorrhage, and vascular anomaly to subarachnoid or intracerebral hemorrhage.

**Clinical Manifestations.** Symptoms of intracranial hemorrhage may be present at birth or may not appear for a variable time after delivery. The commonest symptoms soon after birth are a general failure to move normally, diminished or absent Moro reflex, lethargy and somnolence. Great irregularity of respirations in the absence of other signs of respiratory distress is often a sign of severe hemorrhage. Pallor, cyanosis, cyanotic attacks, failure to suck well, forceful vomiting, anxiety and restlessness, a high-pitched, shrill cry, muscular twitchings, convulsions, or paralyzes may be the first indications that intracranial hemorrhage is present. The fontanel *may* be tense and bulging, and an adder-like protrusion of the tongue may be seen. Retinal hemorrhage, ocular palsies, inequality

in the size of the pupils, failure of them to react to light, or nystagmus may be observed.

**Diagnosis** is based chiefly on the history of delivery, the clinical manifestations and the course. It should be recognized that the nonlocalizing signs of intracranial hemorrhage are identical with those caused by cerebral edema or anoxia, and before carrying out any diagnostic procedure the chance of helping the patient should be weighed against the risk. Subdural taps are usually unrewarding, even in the presence of subdural hemorrhage, since it is likely that the blood will have clotted; on the other hand, they are occasionally lifesaving. Trephining with direct visualization of the meninges is rarely used, owing to the poor condition of most infants in whom the question arises and to the remoteness of the possibility that it will be either diagnostically or therapeutically efficacious. For similar reasons ventricular taps are rarely done even when there is suspicion of intraventricular hemorrhage. Lumbar puncture is definitely indicated in the presence of signs of increased intracranial pressure to identify gross subarachnoid hemorrhage, to rule out the possibility of bacterial meningitis, and possibly to relieve pressure on vital structures.

Since a small amount of bleeding often occurs in the course of normal and even cesarean deliveries, small numbers of red blood cells or slight xanthochromia in sub-

FIG. 75. Bilateral subependymal and intraventricular hemorrhage in a premature infant. The floor of the lateral ventricle is marked by an arrow, outside of which is a large subependymal hemorrhage. (From Arey and Dent., *J. Pediat.*, Vol. 42.)

arachnoid fluid is not necessarily indicative of significant intracranial hemorrhage. Bilirubin may produce a yellowish discoloration of the cerebrospinal fluid in jaundiced infants; conversely, the subarachnoid fluid may be absolutely clear in severe subdural or intracerebral hemorrhage when there is no communication with the subarachnoid space.

**Prognosis.** Death may occur intrapartum in the more severe cases; postnatally, fatalities usually occur within the first three days and result from respiratory failure. If an infant survives, recovery often may be complete, or there may be permanent residuals mainly in the category of cerebral palsy. Presumably some of the membrane-enclosed subdural effusions observed in later infancy may have their origin in subdural hemorrhage at birth. Statistics on incidence and prognosis of intracranial hemorrhage in the newborn are not available, since autopsy material is the only source and since one can rarely be certain of the diagnosis in the surviving patient.

Because the majority of parents are aware of and fear the possibility of cerebral residuals following intracranial hemorrhage or cerebral anoxia, it is probably wisest to give them an opportunity to air their anxiety in a frank discussion of the problem, during which their questions should be invited rather than suppressed or evaded. As optimistic an attitude as possible, consistent with the physician's opinion of the prognosis of the individual case, should be maintained.

**Prevention.** Prophylactic measures exist in better obstetric management; many instances of intracranial hemorrhage are avoidable.

**Treatment.** The infant should be handled as little and as gently as possible. He is best kept in an incubator which allows good temperature control, continuous observation, and easy administration of oxygen for cyanosis. Sodium phenobarbital (8 mg. [ $\frac{1}{8}$  grain]), administered intramuscularly, or other anti-convulsant drugs in appropriate doses, may be used to control convulsive movement. A small dose of vitamin K or, preferably, K<sub>1</sub> oxide should be administered (see Hyperbilirubinemia, p. 334). A small (5 ml. per pound of body weight) transfusion of fresh blood is indicated in the presence of hemorrhagic disease of the newborn. There is lack of agreement about the advisability of performing spinal punctures for the relief of increased intracranial pressure and to remove gross blood in order to reduce its irritant effect on the cerebral cortex and to prevent

possible interference with the normal resorptive mechanisms for cerebrospinal fluid. In our opinion such punctures are indicated, particularly in the presence of grossly bloody spinal subarachnoid fluid.

Neurosurgical procedures are of doubtful advantage; most of them are aimed at relieving pressure which is usually readily accomplished by withdrawal of spinal fluid at lumbar puncture, owing to the relative expandibility of the cranial compartment.

*Cerebral edema* may result in any or all of the clinical signs produced by intracranial hemorrhage. Trauma and anoxia are the usual etiologic factors. Treatment is directed toward relieving increased intracranial pressure, usually by lumbar puncture.

#### SPINE AND SPINAL CORD

Strong traction exerted when the spine is hyperextended or when the direction of pull is lateral may rarely produce fracture and separation of the vertebrae. Such injuries are most likely to occur when difficulty is encountered in delivering the shoulders in cephalic presentations and the head in breech presentations. The injury is most commonly at the level of the seventh cervical and first thoracic vertebrae. Transection of the cord may occur, but hemorrhage and edema may produce neurologic signs indistinguishable from those of transection, except that they are not permanent. There is complete paralysis of voluntary motion below the level of injury, though the persistence of a withdrawal reflex mediated through spinal centers distal to the area of injury is frequently misinterpreted as representing voluntary motion. Severe spinal cord injuries usually cause death soon after birth. In the survivors there is usually permanent partial injury. In compression from a fracture or dislocation the prognosis is related to the time elapsing before the compression is removed.

#### PERIPHERAL NERVE INJURIES

##### BRACHIAL PALSY

Injury to the brachial plexus may cause paralysis of the upper arm with or without paralysis of the forearm or hand. Such an injury occurs when traction is exerted on the head during delivery of the shoulder.

In *Duchenne-Erb's paralysis* the injury is limited to the fifth and the sixth cervical nerves. The infant loses the power to abduct the arm from the shoulder, to rotate the arm externally and to supinate the forearm. The

characteristic position consists in adduction and internal rotation of the arm with pronation of the forearm. The power of extension of the forearm is retained, but the biceps reflex is absent. The Moro reflex is absent on the affected side (Fig. 76). There may be some sensory impairment on the outer aspect of the arm. The power in the forearm and the hand grasp are preserved unless the lower part of the plexus is also injured; the presence of the hand grasp is a favorable prognostic sign. When the injury includes the phrenic nerve, alteration of the diaphragmatic excursion may be observed fluoroscopically.

*Klumpke's paralysis* is a rarer form of brachial palsy; injury to the seventh and eighth cervical nerves and the first thoracic nerve produces a paralyzed hand, and ptosis and miosis, if the sympathetic fibers of the first thoracic root are also injured.

The mild cases may not be detected immediately after birth. Differentiation must be made from cerebral injury, from fracture, dislocation or epiphysial separation of the humerus, and from fracture of the clavicle.

The *prognosis* depends upon whether the nerve was merely injured or was lacerated. If the paralysis was due to edema and hemorrhage about the nerve fibers, there should be

FIG. 76. Brachial palsy of the left arm (asymmetric response to Moro reflex).

FIG. 77. Phrenic paralysis in a newborn infant. The right leaf of the diaphragm is elevated, owing to injury to the right phrenic nerve. Fluoroscopically, the right and left leaves of the diaphragm moved in a "seesaw" manner. There were also fractures of both clavicles and a right brachial palsy.

a return of function within a few months; if due to laceration, permanent damage may result. The involvement of the deltoid is usually the most marked; dropping of the shoulder may result from muscle atrophy.

*Treatment* consists in relaxation of the paralyzed muscles by preventing the antagonistic pull of the nonparalyzed muscles. While the infant is in his crib the wrist can be held by a clove-hitch to the head of the bed so that the arm is maintained abducted and rotated externally, with the elbow flexed. If the hand is paralyzed, padding should be placed in the fist. Later an airplane splint may be used to hold the arm in proper position. Physical therapy is a necessary adjunct to the treatment. If the paralysis persists, because of laceration of the nerve fibers, for two or three months, neuroplasty offers hope for partial recovery.

#### PHRENIC NERVE PARALYSIS

Phrenic nerve injury with diaphragmatic paralysis must be considered when cyanosis and irregular and labored respirations develop. Such injuries are usually associated with a brachial palsy. Breathing is thoracic in type, so that there is no bulging of the abdomen with inspiration. Breath sounds are diminished on the affected side. The *diagnosis* is established by fluoroscopic examination which reveals the elevation of the diaphragm on the paralyzed side and the seesaw movements of the two sides of the diaphragm during respiration. There is no specific *treatment*; the infant should be placed on the involved side; oxygen therapy may be necessary. Feeding by gavage often saves the infant energy for maintenance of the labored respiratory movements. Recovery usually occurs. Pulmonary infections are a serious complication, and prophylactic antibiotic therapy is indicated.

#### FACIAL PALSY

Rarely facial palsy is nonobstetric, resulting from nuclear agenesis of the facial nerve. Usually, however, the paralysis is peripheral and results from pressure over the facial nerve in utero during labor or from forceps during delivery. When the infant cries, there is movement on only one side of the face, and the mouth is drawn to that side. On the affected side the eye cannot be closed and the nasolabial fold is absent. The *prognosis* depends upon whether the nerve was injured by pressure or whether the nerve fibers were torn. Improvement will occur within a few

weeks in the former instance. Care of the exposed eye is essential. Faradic stimulation is probably of no benefit, but neuroplasty may be indicated when the paralysis is persistent.

#### OTHER PERIPHERAL NERVES

Other nerves are seldom injured at birth, except as they are involved in fractures or hemorrhages.

#### VISCERA

The *liver* is the only internal organ other than the brain injured with any frequency. The damage usually occurs from pressure on the liver during delivery of the head in breech presentations. Overzealous manual attempts to apply artificial respiration during resuscitation are a less frequent cause. The injury is rupture of the liver with formation of a subcapsular hematoma. The hematoma may be large enough to cause anemia. Shock and death occur if the hematoma breaks through the capsule, reducing pressure and allowing fresh hemorrhage from the liver. Alertness to the possibility of this condition in infants delivered by breech presentations and in infants who receive manual resuscitation should make it possible to save some of them and to prevent the condition in others.

Although *adrenal hemorrhage* occurs with some frequency, especially after breech delivery, it is not known whether it is traumatic in origin, due to anoxia, or the result of severe stress, as in overwhelming infections. In older infants old calcified central hematomas of the adrenal have been identified at autopsy, suggesting that not all adrenal hemorrhages are fatal. The diagnosis is usually made at postmortem examination. The symptoms are profound shock and cyanosis. If adrenal hemorrhage is suspected, the treatment is the same as for acute adrenal failure (p. 1185).

#### INJURY OF THE STERNOCLEIDOMASTOID

A firm mass 1 to 2 cm. in diameter is occasionally noted in the midportion of the sternocleidomastoid muscle about the second week of life, although it may be present shortly after birth. It is believed by most to be a small hematoma resulting from injury to the muscle at birth, by others to be a fibromatous malformation of the muscle. Contrary to general belief, it does not always result in torticollis to the affected side. The majority of these tumors resolve spontaneously within the first year of life, and any

accompanying torticollis disappears. In the presence of torticollis and as a prophylactic measure the mother can be taught to over-extend the affected muscle by turning the infant's head in the opposite direction and at the same time flexing the neck toward the unaffected side twenty to twenty-five times on two or three occasions daily. This is best done with the baby lying supine on the lap of the sitting mother, the infant's head projecting beyond her knees and his feet against her abdomen. If torticollis persists beyond one to two years, surgical correction may be undertaken.

### FRACTURES

**Clavicle.** The clavicle is fractured more frequently than any other bone and is particularly vulnerable when there is difficulty in delivery of the shoulder. The infant characteristically fails to move, or to move freely, the arm on the affected side, and crepitus may be elicited. The Moro reflex is absent on the affected side, and there is spasm of the sternocleidomastoid muscle with obliteration of the supraclavicular depression at the site of the fracture. In greenstick fractures there may be no limitation of movement and the Moro reflex may be present. Fracture of the humerus or brachial palsy may also be responsible for limitation of movement of an arm and the absence of a Moro reflex on the affected side. The *prognosis* is excellent. *Treatment*, if any, consists in immobilization of the arm and shoulder on the affected side. A remarkable degree of callus develops within a week at the site of the fracture. This may be the first evidence of an unsuspected fracture.

**Extremities.** In fractures of the long bones spontaneous movement of the extremity is usually absent. The Moro reflex is absent from the involved extremity. The possibility of associated nerve involvement must be considered. Satisfactory results for a fractured humerus are obtained by strapping the arm to the chest or applying a Velpeau bandage, and later an airplane splint or a shell cast. For fracture of the femur, good results are obtained with Buck's extension. Splints are effective for treatment of fractures of the forearm or leg. Healing is usually accompanied by excess callus formation.

Dislocations and epiphysal separations rarely result from birth trauma, although epiphysal separations are probably as common as fractures. The upper femoral epiphysis may be separated by forcible manipu-

lation of the infant's leg, as, for example, in breech extraction or after version. There is swelling, slight shortening, limitation of active motion, painful passive motion, and external rotation of the leg. The diagnosis is established roentgenographically. The prognosis is good for the milder injuries, but coxa vara frequently results from extensive displacement.

**Nose.** The most prevalent injury of the nose is a dislocation of the cartilaginous portion of the septum from the vomerine groove and the columella. The infant may have difficulty in nursing and some impairment in nasal respiration. Treatment should be instituted immediately.

### ANOXIA

Anoxia is not a clinical entity, but a term which has been loosely applied to indicate the end result of lack of oxygen from a number of primary causes, some known and some unknown. Separate consideration will be accorded it, however, since it is the leading immediate, though not basic, cause of perinatal death or permanent damage to central nervous system cells which shows up as cerebral palsy and/or mental deficiency in later childhood. Its prevention and treatment are essentially those of the basic conditions which cause it, although death and disability may sometimes be prevented through symptomatic treatment with oxygen or artificial respiration.

*Fetal anoxia* may result from (1) inadequate oxygenation of maternal blood as in cardiac failure or carbon monoxide poisoning, (2) low maternal blood pressure as in the hypotension which may complicate spinal anesthesia, (3) inadequate relaxation of the uterus to permit placental filling as in uterine tetany caused by administration of Pituitrin or Pitocin, (4) inadequate attachment of the placenta as in premature separation of the placenta, (5) impedance to the circulation of blood through the umbilical cord as in compression or knotting of the cord, and (6) placental inadequacy from numerous causes, including toxemia and postmaturity.

After birth, anoxia may result from (1) anemia severe enough to lower the oxygen content of the blood to a critical level as in severe anemia due to hemorrhage or hemolytic disease, (2) shock severe enough to interfere with the transport of oxygen to vital cells as in adrenal hemorrhage, ventricular hemorrhage, overwhelming infection or massive

FIG. 78. Excessive amniotic debris in the lung of a stillborn infant.

blood loss, (3) poisoning of tissue cells so that they are unable to use oxygen as in narcosis from barbiturates or other drugs, (4) a deficit in arterial oxygen saturation due to failure to breathe adequately postnatally, owing to narcosis or cerebral defect or injury, and (5) failure of oxygenation of an adequate amount of blood as in severe forms of cyanotic congenital heart disease or deficient pulmonary ventilation.

Careful studies have failed to show any significant correlation between oxygen content of cord or arterial blood immediately after birth and later intellectual development. Therefore most of the deaths and cerebral damage which result from anoxia are probably related to fetal or postnatal periods of anoxia. The unknown duration of anoxia just before birth or at other times during intrauterine life, body temperature and individual variations in metabolic needs for oxygen are all factors which have probable influence on what constitutes a critical level or duration of anoxia after birth. The known resistance to anoxia demonstrated by newborn infants may be related to oxygen-saving short-cuts in essential metabolic pathways. It is possible that these factors are absent or diminished in individual infants as a result

of deficiency of the enzymes essential for them.

**Clinical Manifestations.** The signs of anoxia in the *fetus* are usually noted a few minutes to a few days before delivery. There is a sudden increase in fetal activity as if the baby were struggling in utero, which may be followed by diminished activity. The fetal heart rate slows, and the beat may become weak and irregular. Particularly in the infant near term, these are signs which should lead to immediate delivery to avoid death or central nervous system damage.

At the *time of delivery* the presence of yellow, meconium-stained amniotic fluid and vernix caseosa is a warning that there has been fetal distress, probably anoxic. Pallor, cyanosis, apnea, slow heart rate, unresponsiveness to stimulation, and muscular flaccidity are definite signs of anoxia.

*After delivery* anoxia is due to respiratory failure and will be discussed under that heading.

**Pathology.** The pathologic changes which result from anoxia per se are principally those caused by congestion and increased capillary permeability. Congestion and petechiae are found in all organs, but are especially noticeable in the pleura, pericardium, thymus, adrenals, brain and meninges. Cerebral edema is common. Gross subarachnoid, intraventricular or adrenal hemorrhage may be present without demonstrable tear of blood vessels. Histologic study of the brain and liver, particularly the right lobe, may show cellular degenerative changes similar to those produced experimentally by anoxia. Fetal anoxia is characterized pathologically by the additional finding of large amounts of amniotic debris in the respiratory passages (Fig. 78).

## RESPIRATORY DISTRESS AND FAILURE

Most disorders of respiration in the newborn infant fall into two principal groups (see Table 59): one resulting from failure of the respiratory center (central nervous system failure) and the other resulting from interference with alveolar exchange of oxygen and carbon dioxide (peripheral respiratory difficulty). The causes of the latter are discussed in the section on Disturbances of the Respiratory Tract. Cyanosis occurs in both central nervous system failure and peripheral respiratory difficulty; the latter merges into the former when anoxia is severe.

Table 59. Respiratory Distress and Failure in Newborn Infants

Type	Manifestations	Examples
Central nervous system failure	Apnea Slow, irregular, gasping respiratory efforts	1. Narcosis 2. Prenatal or paranatal anoxia 3. Intracranial hemorrhage or trauma 4. CNS anomalies
Peripheral respiratory difficulty	Rapid respiratory rate Increasing respiratory rate Chest lag Intercostal retraction Xiphoid retraction Chin tug Expiratory grunt Frothing at lips	1. Primary atelectasis 2. Congestive pulmonary failure 3. Hyaline membrane syndrome 4. Aspiration of meconium-containing amniotic fluid 5. Pneumonia 6. Diaphragmatic hernia 7. Lung cysts 8. Lobar emphysema 9. Pneumothorax 10. Aspiration of food or mucus

CENTRAL NERVOUS SYSTEM FAILURE

*Narcosis* results from heavy doses of morphine, Demerol or barbiturates to the mother shortly before delivery or from maternal anesthesia, especially if prolonged, during delivery. The infant is cyanotic at birth and slow to cry or breathe; when respiration is established, it is extremely slow.

Narcosis is rarely excusable and should be avoided by appropriate analgesic and anesthetic practices.

Treatment consists of physical stimulants such as frequent snapping of the soles of the feet to stimulate crying and deeper breathing, or insertion of a catheter through the nostril into the nasopharynx to produce reflex irritation and breathing. Caffeine with sodium benzoate, U.S.P., 0.5 cc. intramuscularly, may be used as often as every twenty to thirty minutes, if necessary and effective in stimulating the infant. If narcosis is due to morphine or its derivatives, n-allyl normorphine (Nalline), 0.1 mg. per kilogram of body weight, should be injected intravenously. Oxygen should be administered as long as cyanosis is present without it, and some form of artificial respiration may be necessary until

a regular and adequate respiratory pattern is established.

*Prenatal or paranatal anoxia*, whatever the cause, if sufficiently severe, will produce a central nervous system type of respiratory failure. Death is due to apnea in any event, and may be prevented by resuscitation, provided the basic cause of the anoxia can be eliminated within a reasonable time and while artificial respiration, if necessary, is being carried out. As a supplement to resuscitation and removal of the basic cause of anoxia, the use of hypothermia has been advocated, particularly in premature infants, as a means of temporarily reducing metabolic needs for oxygen during the period of oxygen want. Evidence to date is contradictory as to the value of this procedure, and further investigation is needed.

*Intracranial hemorrhage and trauma* (see p. 316).

*Central nervous system anomalies* may produce respiratory failure through a primary maldevelopment of the respiratory center or secondarily through damage to the respiratory center by pressure from a gross anatomic abnormality. It is of interest that immaturity in itself seldom interferes with central respiratory mechanisms.

DISTURBANCES OF ORGAN SYSTEMS

Disturbances of the Respiratory Tract

The various congenital anomalies and localized injuries which may interfere with respiration such as atresia of the anterior or posterior nares, hypoplasia of the mandible

with posterior displacement of the tongue, malformation of the epiglottis, malformations or injury of the larynx, tracheo-esophageal fistula, evulsion of the phrenic nerve

and diaphragmatic hernia are described elsewhere in their appropriate sections.

Here, attention is directed to pulmonary disturbances which give rise to any or all of the symptoms of postnatal respiratory distress as listed in Table 59. Rapid or increasing respiratory rate usually constitutes the earliest and most consistent sign of pulmonary disease in the newborn infant. Notwithstanding the differences listed in Table 59, clinical distinction between intracranial lesions and pulmonary disorders as the cause of respiratory distress or failure is not always clear, and, of course, they may coexist.

### ATELECTASIS

Atelectasis of varying degree is almost constantly present in infants dying shortly after delivery. It is no longer considered to be an adequate explanation for death; careful post-mortem examination usually reveals a cause for persistent atelectasis. Primary atelectasis (failure of initial alveolar expansion), common among premature infants without other apparent abnormality at autopsy, is to be considered due to immaturity of the diaphragm and other respiratory muscles, hypermobility of the thoracic cage, or to other defects of the peripheral respiratory mechanism. It is also seen as a result of brain injury. Secondary atelectasis (alveolar collapse after initial expansion by air) may be seen as a gross or microscopic finding in all types of pulmonary disease in the newborn.

**Pathology.** In the stillborn infant the lungs have a uniformly beefy red appearance. Histologically, the interstitial tissues are congested, and the alveoli present a crumpled sac appearance. The degree of crumpling varies inversely with the amount of expansion of the alveoli by fluid presumed to be amniotic. With sudden anoxia in utero there may be more vigorous inspiratory movements than usual, with an increase in aspiration of amniotic fluid and perhaps also diminished absorption of it from the alveoli. The later in pregnancy this takes place, the more likely is one to find squamous epithelial cells and debris in the alveolar spaces (Fig. 78).

If an infant has breathed, the lungs may show beefy red areas alternating irregularly with lighter, aerated, raised portions. Histologically, the red areas are congested, and the alveolar spaces may be filled with varying amounts of blood or edema fluid. The lighter, aerated portions show varying degrees of distention of alveoli. If there has been vigorous

inspiration, either natural or artificial, one may find irregular areas of overdistention of alveoli. Some of these may have ruptured with resultant interstitial emphysema and, at times, pneumomediastinum and pneumothorax. Whether or not rupture of these overdistended alveoli occurs, they may prevent entrance of air into other parts of the lung.

**Clinical Manifestations.** Cyanosis and poor respiratory exchange on auscultation of the chest are the cardinal signs of atelectasis, which may be confirmed roentgenographically.

**Prevention and Treatment.** Prevention of premature labor, fetal and neonatal anoxia, intracranial hemorrhage, hyaline membrane disease and pneumonia would presumably eliminate most of the causes of atelectasis. Treatment should be aimed at early recognition and proper management of these underlying conditions.

### CONGESTIVE PULMONARY FAILURE

For purposes of identification this term may be arbitrarily applied to infants who show the clinical and pathologic manifestations considered characteristic of hyaline membrane disease, with the exception that hyaline membranes are not found on histologic examination of the lungs.

### HYALINE MEMBRANE DISEASE

Although its acceptance as a clinical and pathologic entity is frequently challenged, hyaline membrane disease is the most widely used term to describe a syndrome of neonatal respiratory distress also designated as abnormal pulmonary ventilation, postnatal asphyxia with atelectasis or perinatal distress syndrome. Pulmonary hyaline membranes are the most frequent pathologic finding in premature infants dying during the first week of life. They are found almost as commonly among full term infants of diabetic mothers and infants born by cesarean section who die with respiratory distress. Occasionally they occur among infants in whom no predisposing factor is apparent.

**Etiology.** It is now widely accepted that hyaline membranes can be produced as the result of (1) effusion from the pulmonary circulation; (2) conversion of fibrinogen in the effusion fluid to fibrin (possibly enhanced by the thromboplastic activity of aspirated amniotic fluid); and (3) syneresis of the

fibrin to form a membrane. Left-sided heart failure, aspiration of regurgitated amniotic fluid present in the stomach at birth, and the use of oxygen have all been proposed as factors contributing to the pathogenesis of the membranes.

**Pathology.** The lungs appear deep purplish-red and noncrepitant. Microscopically, there is extensive atelectasis, engorgement of the interalveolar capillaries, and a number of the alveolar ducts, alveoli and respiratory bronchioles are lined by acidophilic, homogeneous or granular membranes. Amniotic debris, intra-alveolar hemorrhage, pneumonia and interstitial emphysema are additional but inconstant findings (Fig. 79).

**Clinical Manifestations.** Usually the infant with hyaline membrane disease, except for other disturbance, appears normal at birth, but within a few hours, very rarely as long as twenty-four hours, begins to show signs of respiratory distress (see Table 59 for symptoms). In some instances, and especially early in the disease, evidences of emphysema are more striking than are those of atelectasis. When the signs are severe, death occurs within a few hours, but in milder cases the symptoms reach a peak within three days, after which gradual improvement sets in and recovery occurs. On auscultation air exchange usually seems to be within normal limits and rales are rarely heard. When present, they probably signify concomitant pneumonia. Roentgenographically (Fig. 80), the lungs show a reticulogranular appearance which is characteristic but not pathognomonic. It usually disappears with subsidence of respiratory distress, but occasionally persists for one to two weeks. In retrospect most infants who have hyaline membrane disease have shown some evidence of respiratory difficulty, particularly rapid or increasing respiratory rate, during the first hour of life. By using respiratory rates during the first hour or so of life, it is therefore possible to anticipate hyaline membrane disease before sternal retraction, cyanosis and other signs of severe difficulty appear.

**Prognosis.** Since definitive diagnosis can be made only at autopsy, there are no statistics on the prognosis of hyaline membrane disease. When recovery occurs, there are no apparent residuals even though cyanosis has been severe.

**Prevention.** The prevention of prematurity, avoidance of unnecessary cesarean section and careful management of the diabetic mother are the most important factors in the

prevention of hyaline membrane disease. Gastric suction immediately after birth and preferably before the first breath should be performed to prevent possible aspiration of regurgitated amniotic fluid. Although there are conflicting reports as to the benefit of this procedure, it is harmless. Aerosolized water mist with or without wetting, fibrinolytic or proteolytic agents has not been shown to affect the incidence of the disease, nor has the current decrease in the use of oxygen.

**Treatment.** Owing to the frequency of accompanying pneumonia, antibacterial agents, usually penicillin, 100,000 to 200,000 units, and streptomycin, 50 to 100 mg. (except as there is staphylococcal infection in the nursery—see p. 345), according to the size of the patient, may be administered intramuscularly every twelve hours until recovery occurs. Sulfisoxazole should be avoided because it increases the risk of hyperbilirubinemia and kernicterus, and intramuscular preparations of broad-spectrum antibiotics are often poorly absorbed, especially in prematures. Supersaturation of the inspired air with water mist has no advantage over atmospheres of 80 to 90 per cent relative humidity, nor has the inclusion of wetting agents in nebulized water mist been shown to increase its efficacy. Aerosolized proteolytic or fibrinolytic enzymes such as trypsin

FIG. 79. Pulmonary hyaline membranes lining the air spaces of the lung in a premature infant.

FIG. 80. Hyaline membrane syndrome. A diffuse reticulogranular pattern is evident throughout the lungs. The air-containing bronchi are visible by virtue of surrounding nonaerated lung, particularly on the left.

FIG. 81. Fetal distress syndrome.

Figures 80 and 81 show the contrasting radiographic pictures seen in infants with neonatal respiratory distress. Figure 80 shows the uniform reticulogranular pattern consistently seen in but not pathognomonic of hyaline membrane disease. The apparent cardiac enlargement is also characteristic. Figure 81 shows the coarsely granular pattern with irregular aeration typical of fetal distress syndrome (meconium aspiration pneumonia).

and streptokinase-streptodornase to dissolve the hyaline membranes have also been without proved benefit. Moist oxygen should be used only in quantities sufficient to relieve cyanosis when it is present. A few infants in whom cyanosis and respiratory failure could not otherwise be controlled have appeared to respond to the use of the Bloxsum Airlock, although most authorities doubt its efficacy and decry its use. Sternal traction via a suture passed through the xiphoid has been advocated as producing more efficient respiratory efforts, but clinical results are inconclusive. The rocking-bed respirator and a patient-cycled tank respirator, used in conjunction with oxygen, have proponents, but little convincing evidence to support their use in hyaline membrane disease. The same is true of hypothermia.

## PNEUMONIA

Histologic evidence of pneumonia is a frequent finding at autopsy in newborn infants, particularly among those who die after signs

of respiratory distress, even when the primary lesion is obviously cerebral hemorrhage, hyaline membrane disease, aspiration of amniotic contents or feedings, or one of the various forms of emphysema or pneumothorax. Its role as a cause of death is not always clear in such instances, and the clinical manifestations may merge indistinguishably with those of the primary disturbance. Pneumonia does account for about 10 per cent of neonatal deaths.

**Etiology.** Pneumonia in the newborn is caused by bacteria and perhaps by viruses from aspiration of infected amniotic contents or vaginal secretions, through the blood stream, or through the respiratory tract, particularly when there is contact with adults who have respiratory infections. The *Pneumococcus*, beta-hemolytic *Streptococcus* and *H. influenzae*, the commonest acute pulmonary pathogens in older infants and children, are rare etiologic agents of pneumonia during the first two weeks of life, whereas coliform organisms, enterococci, *Klebsiella*, *Pseudomonas*, *Proteus*, *Salmonella* and *Staphylococ-*

cus are common ones. Of these, the coliform organisms are the most frequent, with the *Staphylococcus* second.

**Pathology.** Pneumonia in early infancy is usually bronchopneumonic in type, occasionally interstitial or lobar.

**Clinical Manifestations.** The first signs of pneumonia in the newborn are usually non-specific. They include loss of appetite, listlessness, poor color which may or may not be definable as cyanosis, a rise or sudden fall in body temperature, abdominal distention, sudden loss or gain in weight, and a general impression on the part of the nurse or mother that the baby is doing less well. Cough is inconstant, but almost always means pneumonia when present. A significant increase in respiratory rate, usually to about 80, is a constant and early finding. It, too, should always arouse suspicion of pneumonia. Flaring of the alae nasi, accentuation of the normal irregularity of breathing, and respiratory distress may be present.

**Diagnosis.** Often no physical signs are elicited, although careful auscultation will usually reveal fine, crackling rales which are most commonly heard in the perihilar areas posteriorly, but may be localized in any portion of the lungs. It is important to auscultate the chest with the baby crying as well as quiet, since rales are frequently heard only

at the end of the deep inspirations which come only with crying in the newborn. Areas of hyperresonance may indicate compensatory emphysema. Roentgenograms of the chest are often helpful. Nasopharyngeal and blood cultures are helpful in making an etiologic diagnosis.

For reasons not clear, pneumonia frequently accompanies or follows diarrhea during the first few months of life, and should be kept in mind as a possible complication of enteritis.

**Aspiration Pneumonia.** A history of single or repeated attacks of coughing or apparent choking followed by signs of pneumonia or merely by the infant doing less well than before should suggest the possibility of aspiration pneumonia.

Aspiration pneumonia can be prevented in most instances by care in feeding plus prompt upending of the infant should choking or severe coughing occur during feeding. Small infants should be left lying on their right side or abdomen after feeding rather than on the back. Contents of the stomach should always be aspirated through a soft rubber catheter just before operation or other procedure requiring anesthesia. Procedures which may significantly disturb the infant, and particularly those which interfere with changing the infant to the head-down position, such as

FIG. 82. Staphylococcal pneumonia in an infant 7 months of age. A, The diffuse inflammatory process involving the left lung and pleura is evident. B, Five days later, just before death, there are multiple air-containing cavities in the lung and pleura.

jugular or femoral puncture, lumbar puncture and subdural taps, should be performed at least two hours after a feeding.

*Staphylococcal pneumonia* (see also p. 344) should be suspected in any infant who shows slight and nonspecific untoward signs and who has been exposed to staphylococcal skin infections. Empyema and pneumothorax are frequent complications. The latter constitutes such an immediate threat to life that infants with staphylococcal pneumonia must be watched closely for acute onset of respiratory distress, so that treatment by closed thoracotomy drainage can be carried out without delay.

**Treatment.** Since the usual etiologic organisms are coliforms or staphylococci, chemotherapeutic agents effective against them must be used until a specific bacteriologic diagnosis can be made. Very large doses of penicillin and streptomycin in combination at times are effective even when the organism concerned appears to be insensitive to each of them on laboratory testing. As a single drug, chloramphenicol is the agent of choice, since it is effective against most strains of both coliforms and staphylococci. It has the disadvantage that it probably must be administered orally or intravenously for maximum effect, particularly in premature infants. Once a bacteriologic diagnosis is made, treatment should be directed accordingly. In the presence of known exposure to an epidemic of staphylococcal infection the therapy should include the agent or combination of agents known to be most effective against that particular strain. Gamma globulin may be administered intramuscularly in an attempt to bolster the infant's immune defenses.

## PNEUMOTHORAX AND PNEUMOMEDIASTINUM

Asymptomatic pneumothorax, either unilateral or bilateral, is estimated to occur in as much as 1 per cent of all newborn infants; symptomatic pneumothorax and pneumomediastinum are less common.

**Etiology.** Since pneumothorax is seen frequently among newborn infants who have been subjected to resuscitative measures, it seems likely that the most common cause is overinflation and resulting alveolar rupture. If the ruptured alveoli are on the pleural surface, pneumothorax without pneumomediastinum occurs. If they are not, pulmonary interstitial emphysema results. If the volume

of escaped air is great enough, it is believed to follow the vascular sheaths to the mediastinum, causing mediastinal emphysema. In turn, the mediastinal air may "break" into the pleural space to cause pneumothorax, or into the subcutaneous tissues of the neck and chest to cause subcutaneous emphysema. Ball-valve types of bronchial or bronchiolar obstruction resulting from aspiration may also cause alveolar overinflation which, if mild, produces local emphysema, but, if severe, results in alveolar rupture and pulmonary interstitial emphysema, pneumomediastinum or pneumothorax.

Pneumothorax may also result from direct trauma such as puncture from a broken rib or from rupture of a lung abscess associated with staphylococcal pneumonia. It also occurs from rupture of pulmonary cysts, congenital or acquired. It occurs rarely as a result of alveolar rupture in lobar emphysema.

**Clinical Manifestations.** Localized areas of emphysema frequently seen in roentgenograms of the chest of newborn infants may represent ball-valve bronchial obstruction, pulmonary interstitial emphysema or emphysematous blebs (cysts). The physical findings of asymptomatic pneumothorax are hyperresonance and diminished breath sounds over the involved side of the chest.

Symptomatic *pneumothorax* is characterized by respiratory distress which varies from increased respiratory rate to severe dyspnea and cyanosis. The onset may be sudden or gradual. The chest may appear asymmetric with increased anterior-posterior diameter and bulging of the intercostal spaces on the affected side, and there are hyperresonance and diminished or absent breath sounds. The heart is displaced toward the unaffected side, and the diaphragm is displaced downward. This may produce a finding of apparent hepatomegaly with right-sided pneumothorax. Since both sides may be affected, symmetry of findings does not rule out pneumothorax.

With *pneumomediastinum* the degree of respiratory distress is again dependent on the amount of trapped air. If it is great, there is bulging of the midthoracic area, the neck veins are distended, and the blood pressure is low. The last two findings are the result of blockage of the circulation by compression of the systemic and pulmonary veins. Subcutaneous emphysema in the newborn is almost pathognomonic of pneumomediastinum.

**Diagnosis.** Pneumothorax and pneumome-

FIG. 83. Pneumomediastinum in a newborn infant. Anteroposterior view demonstrates compression of lungs and the lateral view bulging of the sternum, each resulting from distention of the mediastinum by trapped air.

diastinum should be suspected in any newborn infant with respiratory distress; the diagnosis is established roentgenographically (Fig. 83).

**Treatment.** Asymptomatic pneumothorax or pneumomediastinum requires no treatment. If severe respiratory or circulatory embarrassment is present, needle aspiration is indicated. If unsuccessful in maintaining relief of distress, it should be followed by closed thoracotomy with the tube connected to a water trap so that air may escape, but not enter the chest.

## LOBAR EMPHYSEMA

Localized and fixed overdistention of an entire lung, lobe or segment may cause respiratory distress at any time during the newborn period. The condition resembles that due to a check-valve type of obstruction in the bronchus supplying the affected area. Although chondromalacia, bronchial stenosis or web, localized redundancy of bronchial mucosa (valves), endobronchial proliferation of aberrant tissue and external compression by anomalous blood vessels have all been proposed or reported as etiologic factors, no clear cause for lobar emphysema is found in many instances. It causes respiratory distress

through compression of surrounding lung tissue on the same side. If it is severe, the involved area may extend to the opposite side of the chest; the heart is displaced to the opposite side. The physical findings are indistinguishable from those of severe tension pneumothorax, and differentiation from tension pneumothorax and cystic disease of the lung may be difficult even roentgenographically. The treatment is usually surgical removal of the involved area.

## LUNG CYSTS

The great majority of lung cysts during the newborn period are acquired as the result of rupture of alveoli from overinflation or by infection, often staphylococcal; congenital cysts are rare. They may be solitary or multiple, air-containing or filled with fluid, and are believed to result as a developmental anomaly of the bronchial buds. Air-filled cysts on the surface of the lung, whatever their origin, sometimes rupture and cause pneumothorax. This is particularly true of multicystic disease. Since most cystic areas discovered by roentgenologic examination will disappear spontaneously, treatment, which is surgical removal, should be reserved for those which cause severe respiratory distress.

## Disturbances of the Digestive System

### VOMITING

Infants at times vomit mucus, often blood-streaked, in the first few hours after birth. This vomiting infrequently persists after the first few feedings; it may be due to irritation of the gastric mucosa by material swallowed during delivery. If the vomiting is protracted, gastric lavage with physiologic saline solution may relieve it.

Vomiting is a relatively frequent symptom during the newborn period. In the majority of instances it is simply regurgitation from overfeeding or from failure to permit the infant to eructate swallowed air. When vomiting occurs shortly after birth and is persistent, the possibility of increased intracranial pressure or of intestinal obstruction must be considered.

Obstructive lesions occur most frequently in the esophagus (p. 640) and intestines (p. 665). Vomiting from esophageal obstruction occurs with the first feeding. The diagnosis of *esophageal atresia* can be suspected if there is unusual drooling from the mouth and if resistance is encountered in the attempt to pass a catheter into the stomach. There is considerable advantage in establishing the diagnosis before the infant chokes on oral feedings and endangers himself to aspiration pneumonia. *Cardiospasm* is a rare cause of vomiting in the newborn infant; it is demonstrable roentgenographically by obstruction at the cardiac end of the esophagus, without organic stenosis. Regurgitation of feedings due to continuous relaxation of the esophageal-gastric sphincter, *chaliasia*, is an infrequent cause of vomiting, which can be controlled by keeping the infant in a semi-upright position. Vomiting from obstruction of the small intestine usually begins on the first day of life and is frequent, persistent, usually nonprojectile, copious and, unless the obstruction is above the ampulla of Vater, bile-stained; it is associated with abdominal distention, visible deep peristaltic waves, and constipation. Upright roentgenographic films of the abdomen will show the distribution of air in the intestine and often aid in the location of the site of the obstruction; the use of contrast material for these studies is usually unnecessary. Persistent vomiting may occur with congenital hernia of the diaphragm (p. 692) when the viscera are crowded. The

vomiting of *pyloric stenosis* may begin any time after birth, but does not assume its characteristic pattern before the second or third week. Vomiting may occur with many other disturbances which do not obstruct the digestive tract, such as celiac disease, milk allergy, septicemia, meningitis and other infections. It is common with urinary tract infections.

### THRUSH

(ORAL MONILIASIS)

Thrush of the mouth is discussed on page 633. It is mentioned here to emphasize its importance in newborn infants. At this age healthy infants are infected; later, the infection is rare except in debilitated infants and children and those receiving antibiotic therapy.

There is a positive correlation between maternal vaginal and infantile oral moniliasis. The maternal source appears to be the principal primary means of infection in healthy newborns. Secondary cases develop in the hospital nursery, presumably by contact with infected infants and contaminated supplies.

Occasionally a heavy coat forms on the tongue, but its appearance is not that of thrush, nor have cultures from it revealed *Candida albicans*. It can be removed by one or two applications of 1 per cent aqueous solution of gentian violet.

Oral thrush in an otherwise healthy infant is usually a self-limited infection, but treatment is advised (see p. 634). Special sterilization precautions should be taken with nipples, bottles and other materials used by the infant to prevent spread of the infection.

### DIARRHEA

(See pp. 187, 346, 655.)

### CONSTIPATION

More than 90 per cent of newborn infants pass meconium within the first twenty-four hours, and most of the remainder do so within thirty-six hours. Therefore the possibility of intestinal obstruction should be considered in any infant who does not pass meconium within that time. Intestinal atresia or stenosis (p. 665), congenital aganglionic megacolon

(p. 674), meconium ileus or meconium plugs should be suspected. Constipation not present from birth, but appearing during the first month of life, suggests congenital aganglionic megacolon, cretinism or anal stenosis. It must be kept in mind that infrequent bowel movements do not necessarily mean constipation (p. 652). Breast-fed infants may rarely go as long as ten days without a bowel movement and without evidence of discomfort, and then pass a large but otherwise normal stool.

### MECONIUM PLUGS

Anorectal plugs (Fig. 84) of lower water content than normal may be a cause of intestinal obstruction in newborn infants. Rarely a firm mass of meconium may form elsewhere in the intestine and cause intra-uterine intestinal obstruction and meconium peritonitis unrelated to cystic fibrosis of the pancreas. Likewise, anorectal plugs may cause intestinal ulceration and perforation. The plug is usually easily removed by the examining finger, but may require irrigation with isotonic sodium chloride solution or half-strength hydrogen peroxide for evacuation. After removal of a meconium plug the infant should continue to be observed closely for the possible presence of congenital aganglionic megacolon.

### MECONIUM BODIES

These light yellow particles are usually no more than 1 mm. in diameter, but may rarely be large enough to cause distortion of the intestine (Fig. 85). They are occasionally associated with intestinal atresia.

### MECONIUM ILEUS

Impaction of meconium is a relatively rare cause of intestinal obstruction in the newborn infant. It is almost invariably associated with cystic fibrosis of the pancreas. The depletion or absence of the pancreatic ferments prohibits normal digestive activities in the intestinal tract, and meconium is left in a viscid, mucilaginous state. It clings to the intestinal wall and is moved with difficulty or not at all by intestinal peristalsis. Why meconium ileus is a relatively uncommon manifestation of congenital pancreatic deficiency is not clear, but it may be that it occurs only in association with reduction or absence of pancreatic ferments.

The inspissated and impacted meconium fills the intestinal canal, but is most concentrated in the lower ileum. The pancreatic and bile ducts may be plugged by the viscid meconium.

Clinically, the pattern is that of congenital intestinal obstruction with or without intestinal perforation (see Meconium Peritonitis, p. 332). Abdominal distention is prominent, and persistent vomiting soon occurs. Infrequently, one or more inspissated meconium stools may be passed shortly after birth.

The *differential diagnosis* involves other

FIG. 84.

FIG. 85.

FIG. 84. Anorectal plug, from child who had not passed meconium for 2 days after birth, is indistinguishable from normal plug. Pale end was adjacent to anus.

FIG. 85. Cecum with large meconium bodies. (From J. L. Emery: Abnormalities in Meconium of Fetus and Newborn. Arch. Dis. Childhood, Vol. 32.)

FIG. 86. Meconium ileus. Impacted meconium with small amounts of air interspersed throughout it in loops of intestine on right side of abdomen; intestinal loops above this impaction are greatly distended.

causes of intestinal obstruction; an exact diagnosis cannot be made except by laparotomy. A presumptive diagnosis can be made on the basis of a history of cystic fibrosis of the pancreas in a sibling, by palpation of doughy or cordlike masses of intestines through the abdominal wall and by the roentgenographic appearance. In contrast to the generally evenly distended intestinal loops above an atresia, the loops may vary in width and not be as evenly filled with gas. At points of heaviest meconium concentration the infiltrated gas may create a granular appearance (Figs. 86, 87).

The case fatality rate is high, but a number of infants have survived the neonatal period; their subsequent prognosis is dependent upon the basic disturbance, cystic fibrosis of the pancreas.

*Treatment* is surgical. A number of operative techniques have been used. Gross recommends the so-called Mikulicz resection of the terminal portion of the ileum, with a temporary double ileostomy through which the intestine can be lavaged with dilute hydrogen peroxide solution.

### MECONIUM PERITONITIS

Perforation of the intestine may occur in utero or shortly after birth. The tear may be sealed by natural processes relatively quickly with only a small amount of meconium escaping, or the meconial contents may largely

be emptied into the peritoneal cavity. Such perforations occur most often as a complication of meconium ileus in infants with cystic fibrosis of the pancreas, but occasionally the perforation is due to a meconium plug, meconium bodies or intestinal obstruction of whatever cause.

When the intestinal perforation is spontaneously sealed with the escape of only a small amount of meconium, and there are no subsequent signs of intestinal obstruction or peritonitis, the event may never be known, or, if some of the meconial particles become calcified, they may subsequently be discovered fortuitously on roentgenograms of the abdomen. Otherwise the clinical picture is dominated by the signs of intestinal obstruction and/or peritonitis. Characteristically, there are abdominal distention, vomiting and absence of stools. The treatment is primarily elimination of the intestinal obstruction and drainage of the peritoneal cavity. Supportive fluid therapy is detailed on page 186.

### JAUNDICE IN THE NEWBORN INFANT

**Etiology.** Recent investigations have shown that lipid-soluble bilirubin (indirect-reacting) must be converted to water-soluble glucuronides of bilirubin (direct-reacting) before it can be excreted in either bile or urine. This conversion appears to require adequate amounts of an enzyme, tentatively named bilirubin transferase. However, there is some evidence that this enzyme may not be specific for the conversion of bilirubin, but is concerned with glucuronic acid conjugation in general and might be more accurately labeled glucuronic acid conjugase. The enzyme seems to be present either in small amounts or in an inactive state in newborn infants, particularly in premature infants. Therefore any factor which increases the load of bilirubin to be metabolized by the liver (erythroblastosis fetalis, other hemolytic anemias, infection), any factor which may damage or reduce the activity of the enzyme (anoxia, infection, possibly hypothermia and thyroid deficiency), any factor which may compete for or block the enzyme (drugs and other substances requiring glucuronic acid conjugation for excretion) or any factor leading to absence or decreased amounts of the enzyme (genetic defect, prematurity) may be expected to cause or increase the degree of jaundice. Since most neonatal jaundice is due to increased serum levels of indirect-reacting bilirubin, it is logical to expect that

the magnitude of these levels will be dependent on the degree and duration of deficiency of this enzyme.

**Clinical Manifestations.** Jaundice may be present at birth or may appear at any time during the neonatal period, depending on the condition responsible for it. Its intensity bears no dependable relationship to the degree of hyperbilirubinemia. Jaundice resulting from deposition of indirect bilirubin in the skin tends to appear bright yellow or orange; jaundice of the obstructive type (direct bilirubin), a greenish or muddy yellow. This difference is usually apparent only in severe jaundice. The infant may be lethargic, feed poorly and become dehydrated.

**Differential Diagnosis.** Jaundice present at birth or appearing within the first twenty-four hours of life should be considered due to erythroblastosis fetalis (p. 955) until proved otherwise; cytomegalic inclusion disease (p. 524) and congenital toxoplasmosis (p. 616) are other rather infrequent possibilities. Jaundice which first appears on the second or third day is usually "physiologic," but may represent the more severe form now called hyperbilirubinemia of the newborn. Familial nonhemolytic icterus also is seen initially on the second or third day. *Jaundice appearing after the third day and within the first week should suggest septicemia as the*

*most likely cause; it may be caused by other infections, notably syphilis, toxoplasmosis and cytomegalic inclusion disease.*

Neonatal jaundice initially noted after the first week of life suggests congenital atresia of the bile ducts (p. 714), homologous serum hepatitis, herpetic hepatitis, idiopathic dilatation of the common bile duct (p. 714), galactosemia (p. 274), congenital hemolytic anemia (spherocytosis) or possibly the crises of other hemolytic anemias such as thalassemia, sickle cell disease, hereditary nonspherocytic anemia or hemolytic anemia due to idiosyncrasy to drugs or other substances.

Persistent jaundice during the first month of life suggests the so-called inspissated bile syndrome, which may follow erythroblastosis fetalis, hepatitis, cytomegalic inclusion disease, syphilis, toxoplasmosis, familial nonhemolytic icterus (p. 702), congenital atresia of the bile ducts, idiopathic dilatation of the common bile duct, or galactosemia. Rarely, physiologic jaundice may be prolonged for several weeks. When this occurs, the possibility of cretinism should also be considered.

**Physiologic Jaundice (Icterus Neonatorum).** Since so-called physiologic jaundice now appears to be due to a temporary metabolic defect, the term is misleading and should be discarded. The usually slight degree of jaundice which is clinically visible

FIG. 87. Meconium ileus. A, Multiple loops of distended bowel are evident. On the right side of the abdomen a large section of small intestine containing inspissated meconium is suggestive of a solid mass. The meconium is characteristically interspersed with small bubbles of air, creating a granular appearance. The large loops of distended bowel in the pelvis proved to be loops of ileum. B, The colon is outlined by contrast material. The colon is small because meconium has not reached it as is the case in meconium ileus or atresia of the ileum. The small circumscribed radiolucencies in the colon represent air injected with the contrast material and mucus present in the colon.

**Table 60.** Relation of Maximum Total Serum Bilirubin Concentration to Incidence of Kernicterus

Maximum Bilirubin Concentration (Mg./100 Ml.)	Kernicterus
10-18.....	0
19-24.....	7%
25-29.....	30%
30-40.....	70%

Adapted from Mollison and Cutbush: Recent Advances in Paediatrics. London, J. & A. Churchill, Ltd., 1954, p. 112.

on the second or third day in about two thirds of full term newborn infants and which ordinarily disappears between the fifth and the seventh days of life is termed physiologic jaundice. It is dependent on the normal neonatal rise in serum bilirubin level which, in turn, is believed to be the result of the breakdown of fetal red cells combined with transient deficiency of bilirubin transferase in the liver. Among premature infants this rise in serum bilirubin tends to be a little slower and of longer duration, resulting in generally higher levels, the peak being reached between the fourth and seventh days; peak levels in term infants usually occur on the second or third day of life.

**Hyperbilirubinemia of the Newborn.** When total serum bilirubin levels reach 18 to 20 mg. per 100 ml. during the first week of life, bilirubinemia beyond "physiologic" bounds (hyperbilirubinemia) is considered to be present. This may occur as an exaggeration of "physiologic" jaundice, particularly in prematures, or as a result of excessive hemolysis, as in erythroblastosis fetalis. The term *hyperbilirubinemia of the newborn*, however, should be reserved for those infants whose primary problem is a deficiency or inactivity of bilirubin transferase rather than an excessive load of bilirubin for excretion. Serum bilirubin may reach the alarming level of 60 to 70 mg. per 100 ml. in full term or premature infants in the absence of any blood group incompatibility.

The *significance* of hyperbilirubinemia lies in the high incidence of kernicterus associated with serum bilirubin levels over 18 to 20 mg. per 100 ml. and the fact that this condition rarely occurs in infants who do not have levels of that magnitude. The correlation between serum bilirubin levels and kernicterus in infants with erythroblastosis fetalis (Table 60) undoubtedly holds for infants without blood group incompatibilities.

The *incidence* of hyperbilirubinemia among term infants without blood group incompatibility is about 5 per cent; among premature infants without blood group incompatibility it varies from 10 to 40 per cent in different series. Because the incidence of kernicterus varies from 2 to 16 per cent of all autopsies done on premature infants, there is little doubt that factors other than the initial unavailability of bilirubin transferase play a role. Some of these factors are known. Vitamin K analogues (72 mg. to the mother during labor and 10 to 30 mg. to infants over the first few days of life) are associated with a high incidence of hyperbilirubinemia. Sulfisoxazole (Gantrisin) predisposes to the development of kernicterus in premature infants at relatively low serum bilirubin levels. Prolonged neonatal cyanosis, bacteremia and a diabetic mother predispose the infant to hyperbilirubinemia. Negro infants appear to be less susceptible, but studies to date deal only with babies premature by weight, and it is well known that Negro infants tend to weigh less than white infants of the same gestational age. Since hyperbilirubinemia is related to short gestational age rather than to low birth weight, the supposed difference between white and Negro infants may be more apparent than real.

**Inspissated Bile Syndrome.** In a few infants with erythroblastosis fetalis and marked hyperbilirubinemia the icterus persists and is associated with a significant and increasing elevation of direct as well as of indirect bilirubin. It is not known whether this condition occurs in association with hyperbilirubinemia due to deficiency of bilirubin transferase. It has been postulated that the syndrome is the result of obstruction from swollen liver parenchymal cells damaged by erythroblastosis. An alternate theory is that the hemolytic process produces an overload of bile pigment causing stasis and blockage in the intrahepatic ducts, particularly in the presence of dehydration. Its onset appears to be too early to be the result of homologous serum hepatitis acquired through the blood used for transfusion of the erythroblastotic infant, and it has become increasingly rare with the more liberal use of repeated exchange transfusions to lower serum bilirubin levels. The obstruction and jaundice clear spontaneously within a few months, and there is no mortality related to it; the possibility of neurologic damage must be considered.

**Neonatal Hepatitis.** About 25 per cent of cases of prolonged obstructive jaundice in

infancy are due to neonatal hepatitis with onset during the first few weeks of life. The etiology is not clear, since it is rarely, if ever, associated with hepatitis in the mother during pregnancy. It is most likely caused by the virus of homologous serum hepatitis, the mother being a carrier. A few cases of hepatitis and icterus caused by generalized infection with the virus of herpes simplex (p. 493) have been reported. Hepatitis is characterized by jaundice chiefly of the obstructive type, acholic stools, dark urine and moderate hepatomegaly and splenomegaly. Microscopic examination shows great variation in the size of liver cells, and multinucleated giant cells are diffusely distributed throughout the lobules.

Clinically it is impossible to differentiate neonatal hepatitis from congenital atresia of the bile ducts, idiopathic dilatation of the common bile duct or inspissated bile syndrome following erythroblastosis fetalis, although a history of severe hemolytic disease of the newborn strongly suggests the last. Differentiation on the basis of cephalin flocculation and thymol flocculation and turbidity tests is impossible because these usually give normal results in all four conditions. Administration of cortisone orally for ten days may be helpful diagnostically. It will occasionally relieve the obstructive factor in neonatal hepatitis and dramatically lower the serum bilirubin. Its effect on the ultimate course of the disease remains to be determined; it has no effect on prolonged obstructive jaundice from other causes in early infancy, and it should probably be avoided in herpetic hepatitis. Close observation of the infant and the pattern of his bilirubinemia for one month will on occasion clarify the diagnosis and probably will not harm the infant with surgically remediable biliary tract obstruction. If the diagnosis is still in doubt, a small abdominal incision should be made, a cholangiogram obtained after injection of dye into the gallbladder and a biopsy of the liver obtained. Extensive surgical exploration carries too high a mortality rate for the relatively frequent patient with neonatal hepatitis to

justify it as a means of early discovery and treatment of the rare instances of surgically reconstructive extrahepatic biliary malformations. About two thirds of infants with neonatal hepatitis recover completely, about 20 per cent succumb, and the others suffer cirrhosis of the liver. No specific treatment is available.

**Kernicterus.** The pathology and clinical manifestations of kernicterus, one of the principal causes of neurologic abnormalities, are described on pages 958 and 1077. Most studies suggest that kernicterus results from deposition of indirect-reacting bilirubin in brain cells. This rarely occurs with serum levels of indirect bilirubin under 20 mg. per 100 ml., and it appears that such levels must be maintained for at least twenty-four hours for kernicterus to occur. Any factor which tends to produce or prolong high serum indirect bilirubin levels increases the incidence of kernicterus.

**Prevention and Treatment.** Except for physiologic jaundice, icterus in the newborn is, as has been indicated, usually a sign of some other disease, and the treatment is that of the basic condition. However, jaundice itself requires treatment when bilirubinemia reaches levels at which kernicterus is a risk. At present, treatment consists of exchange transfusions repeated as frequently as necessary to keep indirect bilirubin levels under 20 mg. per 100 ml. After four to six transfusions the increasing risk of complicating infection, the technical difficulties and the apparent futility of the procedure usually justify cessation of treatment. A more logical approach is through avoidance of the use of sulfisoxazole, high doses of vitamin K, anoxia, prematurity and other at present unknown factors which may predispose the infant to kernicterus or to toxic levels of serum bilirubin. Prevention of hyperbilirubinemia through the early administration of substances designed to enhance the pathways for metabolism and excretion of bilirubin is still in the experimental stage, but offers promise.

## *Disturbances of the Blood*

### **ANEMIA IN THE NEWBORN INFANT**

Anemia at birth is manifest by pallor or shock. It is usually caused by hemolytic disease of the newborn (p. 955), but may also be the result of tearing or cutting of the umbilical cord during delivery or of hemor-

rhage from the fetal side of the placenta. The last may be caused by accidental incision of the placenta in the course of cesarean section or by so-called transplacental hemorrhage. Anemia at birth may also be seen in one of twins with conjoined placental circulation, in which case the anemic twin "bleeds into"

the other, who is larger and polycythemic.

*Transplacental hemorrhage* (see p. 943) with bleeding from the fetal into the maternal circulation is probably more common than is generally recognized, but is usually not sufficient to cause clinically apparent anemia at birth. The etiology of transplacental hemorrhage is not clear, but the condition has been proved as an entity through the demonstration of significant amounts of fetal hemoglobin and of red cells from the baby in the maternal blood on the day of delivery. This condition is the only proved means by which fetal red cells enter the maternal circulation to cause production of antibodies which result in hemolytic disease of the newborn.

Anemia appearing in the first few days after birth is most frequently the result of hemolytic disease of the newborn. Other causes are obvious hemorrhage as in hemorrhagic disease of the newborn and bleeding from an improperly tied or clamped umbilical cord; large cephalhematomas, which are a frequently unrecognized source of anemia during the newborn period; and intracranial hemorrhage or subcapsular bleeding from rupture of the liver (p. 320). Rapid decreases in hemoglobin or hematocrit values during the first few days of life may be the initial clue to either of the two last-named conditions.

Later in the newborn period delayed anemia from hemolytic disease of the newborn, with or without exchange transfusion, may be seen. Vitamin K (as Synkavite) in large doses has recently been considered a cause of anemia in premature infants characterized by inclusion bodies (Heinz bodies) in the erythrocytes. Congenital hemolytic anemia (spherocytosis) occasionally makes its appearance during the first month of life, and hereditary nonspherocytic hemolytic anemia in a newborn infant has been described. Bleeding from hemangiomas of the upper gastrointestinal tract or from ulcers caused by aberrant gastric mucosa in a Meckel's diverticulum or duplication are rare sources of anemia in the newborn.

Since further "physiologic" fall in erythrocyte and hemoglobin content is to be expected in all newborn infants (p. 932), *treatment* consists not only in removing the source of the anemia, if it is still present, but also in whole blood transfusion which probably should be mandatory for hemoglobin levels below 8 gm. per 100 ml. There is inconclusive evidence that early feeding of red

meats or administration of intramuscular iron may be effective in enabling anemic infants to show an increase rather than a decrease in erythrocyte and hemoglobin concentrations before the second or third month of life.

## HEMORRHAGE IN THE NEWBORN INFANT

*Hemorrhagic disease of the newborn* is a rare condition characterized by a tendency to spontaneous and prolonged bleeding, especially from the gastrointestinal tract or into the central nervous system, between the second and fifth days of life. The skin, umbilicus, conjunctiva, retina, nose, mouth, lungs and genitourinary tract may be other sites of bleeding. The disease has been thought to be related to the deficiency in prothrombin which is present during the first five days of life. Routine administration of small amounts of vitamin K to the mother in labor or to the newborn infant will correct the deficiency of prothrombin and appears to have reduced the frequency of hemorrhagic disease of the newborn. This exogenous vitamin K is presumed to supply the infant's needs until his intestinal bacterial flora is sufficiently established to supply the normal needs of this substance.

The actual relation of prothrombin and vitamin K deficiencies to hemorrhagic disease of the newborn is uncertain, and it is thought that there may be an unknown additional factor. An identical clinical picture may result from PTA (plasma thromboplastin antecedent) deficiency and probably from AHG (antihemophilic globulin) or PTC (plasma thromboplastin component) deficiency, or from afibrinogenemia or other congenital defects in blood coagulation.

In infants with hemorrhage not obviously related to trauma or anoxia an attempt should be made to identify any coagulation defect which may be present, and to carry out treatment as indicated. In the presence of severe bleeding in apparent hemorrhagic disease of the newborn a small transfusion (10 ml. per kilogram of body weight) of fresh compatible blood will stop the bleeding promptly if it is due to prothrombin deficiency or to one of the various types of hemophilia. Vitamin K administration is useful only in prothrombin deficiency due to lack of vitamin K, and there is a lag of several hours in its effect, so that it is of doubtful value in hemorrhagic emergencies.

The so-called *swallowed blood syndrome*, in which blood or bloody stools are passed, usually on the second or third day of life,

may be confused with hemorrhage from the gastrointestinal tract, or *melena neonatorum*. The blood may be swallowed during delivery or from a fissure in the mother's nipple. Differentiation from gastrointestinal hemorrhage is based on the fact that the infant's blood contains mostly fetal hemoglobin, which is alkali-resistant, whereas swallowed blood from a maternal source contains adult hemoglobin, which is promptly changed to alkaline hematin upon the addition of alkali. Apt has devised the following test for this differentiation:

(1) Rinse a blood-stained diaper or some grossly bloody stool with a suitable amount of water to obtain a distinctly pink supernatant hemoglobin solution. (2) Centrifuge the mixture. Decant the supernatant solution. (3) To five parts of the supernatant fluid add one part of 0.25 normal (1 per cent) sodium hydroxide. Within one to two minutes a color reaction takes place: a yellow-brown color indicates that the blood is maternal in origin; a persistent pink, that it is from the infant. A control test with known adult or fetal blood, or both, is advisable.

*Congenital thrombocytopenic purpura* (p. 976) may occasionally be confused with hemorrhagic disease of the newborn. It usually occurs in the infants of mothers with thrombocytopenia or possibly of those who have been sensitized to platelet antigens by previous transfusion or pregnancy. The labo-

ratory findings are those of thrombocytopenic purpura. The mother will in each instance have platelet agglutinins in her serum. Infants of mothers with thrombocytopenic purpura should be observed carefully for hemorrhage. Conversely, thrombocytopenia in the infant may be the first clue to the disease in the mother. The platelet agglutinins usually disappear from the baby's blood in a few days or weeks, and the platelet count returns to normal.

The widespread subcutaneous ecchymoses frequently seen in premature infants at or immediately following birth are apparently a result of *fragile superficial blood vessels* rather than of a coagulation defect. In any event vitamin K administration to the mother during labor seems to have little effect on their incidence. An occasional infant is born with petechiae or a generalized bluish suffusion limited to the face, head and neck. These are probably the result of *venous obstruction* caused by sudden increases in intrathoracic pressure during delivery. It may take two to three weeks for such suffusions to disappear.

Generalized petechiae suggest thrombocytopenia or infection. Acute leukemia is an exceedingly rare cause. Cytomegalic inclusion disease and syphilis should always be considered.

## Disturbances of the Genitourinary System

See also section on Genitourinary System.

One or both kidneys are often easily palpable in the newborn infant since the lower pole normally lies at the level of the pelvic brim. When both are palpable, there is usually no particular diagnostic problem, but when only one kidney can be felt, it frequently gives the impression that it is larger than normal or represents or is displaced by an intrinsic or extrinsic mass. Marked fetal lobulation may contribute to the impression of abnormality. Usually the problem resolves itself as the kidney becomes progressively less easily palpable during the early months of life. Since palpable enlargement or displacement of the kidney in the newborn may rarely be due to an embryoma, polycystic disease or hydronephrosis, an abdominal scout film and/or intravenous urograms are indicated if there is serious question about the nature of the palpable mass. Owing to the poor concentrating ability of the neonatal kidney, relatively large amounts of the con-

trast material (10 to 20 cc. of Diodrast) must be injected to get satisfactory films. Elevations of blood urea nitrogen may be seen during the newborn period in association with polycystic disease and hydronephrosis without necessarily implying a poor prognosis.

During the newborn period moderate elevation of the blood urea or nonprotein nitrogen is common and does not necessarily signify renal disease. The urine may contain casts and cellular elements which are apparently a manifestation of dehydration, since they are most often seen in dehydrated infants and disappear with the ingestion of adequate amounts of fluid.

### BILATERAL RENAL AGENESIS

Infants with bilateral renal agenesis have a characteristic facies (Potter): a general appearance of premature senility, a mild increase in width between the eyes, with a prominent fold of skin arising at the inner

canthus and extending downward and laterally below the eyes to form a wide semicircle, and unusual flattening and slight broadening of the nose, a recession of the chin, and large, low-lying ears with incomplete cartilaginous development. There is usually a diminished quantity of amniotic fluid, presumably due to lack of urine formation. At autopsy there is no evidence of the ureters or kidneys. Pulmonary hypoplasia has also been observed. The anomaly has occurred predominantly in male infants. In some of the female infants there has been failure of development of the uterus and the vagina, the gonads and the fallopian tubes being present. In male infants the prostate, seminal vesicles, ductus deferens and testes are normally formed. The bladder is a tubelike structure with little musculature. The rudimentary

adrenal glands are normal. The outlook is hopeless, the infant dying during labor or shortly after birth.

### URINARY TRACT INFECTION

In contrast to the sex distribution in later infancy, pyuria may occur more frequently in the male than in the female newborn infant. The etiologic agent is usually the colon bacillus, although it may be any of the urinary tract pathogens.

The symptoms may be vague; on occasion they are predominantly gastrointestinal. Fever, difficulty in feeding and failure to gain weight are commonly encountered; jaundice and meningismus are occasional features. There may be urinary suppression.

For diagnosis and treatment see page 1032.

## *Disturbances of the Cranium*

(See also Hydrocephalus, Anencephaly, Microcephaly and Craniosynostosis).

### CRANIOTABES

(CONGENITAL CRANIAL OSTEOPOROSIS)

Palpation of the skull of the newborn infant may reveal areas of softening along the suture lines, especially in the parietal area, which indent from pressure of the fingers with the resilience of a Ping-pong ball. This phenomenon is demonstrated more frequently in premature infants, but occurs in 10 to 35 per cent of all newborn infants. The failure to observe it in breech presentations has led to

an assumption that it may be due to intra-uterine pressure against the maternal pelvis. This condition is a harmless and physiologic result of incoordination between the rapid growth of the brain and the calcification processes in the vertex in the last month of gestation and is associated with a generalized osteoporotic process in the newborn infant. Differentiation must be made from the craniotables of rickets, from lacunar skull, in which honeycombed areas of porotic bone create a characteristic appearance in the roentgenogram of the skull, and from osteogenesis imperfecta.

## *Disturbances of the Skin*

Skin conditions which occur in older as well as in newborn infants are discussed in the section on The Skin. For Erysipelas, see page 410.

### LOCALIZED SKIN DEFECTS

Congenital skin defects may occur on various parts of the body, but especially on the scalp and along the vertebral column. The scalp defects vary in size up to a centimeter or so and may occur in the midline or over the parietal bones; they are at times mistaken for obstetric injuries. There is no hair over the involved portion, since the defect extends

through the dermal layer and, on occasion, into the deeper tissues, including the meninges. On the scalp and along the vertebral column they have their greatest significance when a sinus tract extends to the meningeal space. Such a defect and its sinus tract constitute an entry for meningeal infection and should be removed surgically as a prophylactic measure.

### ERYTHEMA TOXICUM

Erythema toxicum is a transient, blotchy erythematous rash occurring predominantly in the first few days of life. Characteristically,

there is a small whitish wheal in the center of the erythematous areas. The lesions develop on any part of the body, but especially on the back, the shoulders and the buttocks. The cause is obscure. The rash has been attributed to contact from clothing, to irritation from oil or soap and to a hypersensitivity to human or cow's milk or other allergens. The rash is likely to change remarkably within a few hours. There are no general symptoms, and no treatment is necessary.

## MILIA

Milia (see also p. 1280) occur commonly on the face of the newborn infant; they are pinpoint-sized, white spots which result from retention of sebaceous material within the sebaceous glands. They are especially prominent on the nose and chin, but occur on other parts of the face and on the body. They usually disappear with the normal process of desquamation in the newborn period.

## IMPETIGO NEONATORUM

See also Staphylococcal Infections (p. 344).

Impetigo neonatorum is presumably caused by staphylococci or streptococci. The source of the infection in a hospital nursery is often not determined; outbreaks have been attributed to a skin lesion of the mother or an attendant. Lesions not distinguishable from impetigo neonatorum have been noted at birth; their etiology is unknown.

The lesion is a superficial vesicle on a

FIG. 88. Impetigo neonatorum.

reddened base surrounded by an erythematous areola. The blister is often wrinkled, but contains some fluid and is easily denuded by slight trauma, usually without formation of crusts (Fig. 88). The lesions tend to appear on moist or opposing surfaces of the skin, as under the abdominal band or diaper, in the groin, in the axilla and in the folds of the neck. Serious local lesions are not common, and constitutional manifestations are rare.

Impetigo neonatorum is important principally because it is contagious. On rare occasions septicemia and pemphigus occur as complications. All infants in a hospital nursery who contract impetigo should be isolated. Local therapy which tends to macerate the skin is contraindicated. The exfoliated epidermis should be removed with alcohol on cotton and the denuded area exposed to dry heat. Rapid control of the infection may be obtained with bacitracin ointment. Most impetiginous lesions heal without scarring; only the larger, deeper ones are likely to leave scars.

## PEMPHIGUS NEONATORUM

The term "pemphigus" is applied to superficial bullous lesions of severe impetigo widely distributed over the surface of the body, with the exception of the palms and soles. The absence of lesions on the palms and soles serves as a differentiation from syphilitic pemphigus. The constitutional reaction is usually severe, and the prognosis is serious. Recovery can be expected, however, if antibiotic therapy is started early. Penicillin should be administered systemically after blood for bacterial culture has been secured.

## PARONYCHIA

Sucking of the thumb or finger is a common habit in newborn infants, possibly because of the active sucking reflex and the sensitivity of the lips. Maceration or traumatization from the sucking may predispose to infection with the development of paronychia or onychia. Mittens may be worn as a prophylactic measure. In the early stage of infection, cleansing with alcohol and application of bacitracin ointment may avert the need for surgical treatment.

Paronychia congenita is described on page 1276.

## MASTITIS NEONATORUM

Engorgement of the breasts is physiologic in newborn infants. Infection may be abetted by undue manipulation of the breasts and is manifest by redness, local heat, swelling and pain. Fever and other general symptoms may also be present. The prognosis is favorable unless septicemia develops. Prophylaxis con-

sists in avoidance of manipulation or other trauma of the engorged breasts. Treatment includes systemic antibiotic therapy and hot compresses applied locally. If an abscess develops, it should be incised and drained. Sequels from scar formation include impairment of the secreting power of the mammary gland in later life and distortion of the nipple.

## Disturbances of the Eye

These are discussed in the section on The Eye. See Conjunctivitis, Obstruction of the

Nasolacrimal Duct, Cataract and Retrolental Fibroplasia.

## The Umbilicus

**Umbilical Cord.** The cord contains the two umbilical arteries, the vein, the rudimentary allantois, the remnant of the omphalomesenteric duct and a gelatinous substance called the jelly of Wharton. The sheath of the umbilical cord is derived from the amnion. The arteries have a strong contractile capacity, whereas that of the vein is less, and as a result it retains a fairly large lumen after birth. When the cord sloughs, portions of these structures remain in the base. The blood vessels are functionally closed, but are patent anatomically for twenty to twenty-five days. The arteries become the lateral umbilical ligaments; the vein, the ligamentum teres; and the ductus venosus, the ligamentum venosum. During this interval the umbilical vessels are potential portals of entry for infection.

**Types of Navel.** There are three types of navels: normal, amniotic and the skin or cutis navel. When the skin of the abdominal wall meets the umbilical cord at the level of the abdomen, there remains only a small amount of skin at the base when the cord sloughs, and a *normal* umbilical cicatrix results. If the skin does not extend to the base of the cord and the amniotic membrane must cover the skin surface adjacent to the base, a small superficial ulcer will result which closes in by granulation and leaves the flat scar of the *amniotic* navel. When the skin extends up the sides of the cord, a protruding stump, the *skin* navel, remains after the cord has sloughed. The protrusion of the skin or cutis navel must be differentiated from a postnatal hernia, with which, of course, it can be associated; a skin navel, per se, does

not have a defect in the abdominal wall and therefore is not exaggerated when the infant strains or cries. Usually the cicatrix shrivels, so that eventually the skin navel becomes less prominent.

## ANOMALIES

*Patency of the omphalomesenteric duct* may be responsible for an intestinal fistula, prolapse of the bowel, polyp or a Meckel's diverticulum. If a portion of the umbilical vessels remains patent, there may be a fistula, or intestinal obstruction may result.

A *persistent urachus* (urachal cyst) is due to failure of closure of the allantoic duct. Patency should be suspected if there is a clear, light yellow, urine-like discharge from the umbilicus. Methylene blue, injected subcutaneously or given orally, can be recovered from the umbilical wound if a connection to the urinary bladder exists and permits discharge of urine through the navel.

## CONGENITAL OMPHALOCELE

An omphalocele is a herniation or protrusion of abdominal contents into the base of the umbilical cord. In contrast to the more common umbilical hernia, the sac is covered merely with peritoneum without overlying skin. The size of the sac which lies outside the abdominal cavity depends upon its contents. It has been estimated that there is herniation of intestines into the cord in about one of 5000 births and of liver and intestines in one of 10,000 births. The abdominal cavity is proportionately small, owing to deficient impulse to grow and develop.

Immediate surgical repair, before infection has taken place and before the tissues have been damaged by drying or the sac has ruptured, is the only possibility for the infant's survival.

## TUMORS

Tumors of the umbilicus are rare; they include angioma, enteroteratoma, dermoid cyst, myxosarcoma and cysts of urachal or omphalomesenteric duct remnants.

## HEMORRHAGE

Hemorrhage from the umbilical cord may be due to trauma, to inadequate ligation of the cord or to failure of normal thrombus formation. Hemorrhage may also be an evidence of hemorrhagic disease of the newborn, septicemia or local infection. The infant should be observed frequently during the first few days of life so that, if hemorrhage does occur, it will be detected promptly.

## GRANULOMA OF THE UMBILICUS

The umbilical cord usually dries and separates within six to eight days after birth. The raw surface becomes covered by a thin layer of skin, scar tissue forms, and the wound is usually healed within twelve to fifteen days. The presence of saprophytic organisms delays separation of the cord and increases the possibility of invasion by pathogenic organisms. Mild infection may result in a moist granulating area at the base of the cord with a slight mucoid or mucopurulent discharge. Good results are usually obtained by cleansing with alcohol several times daily.

The persistence of exuberant granulation tissue at the base of the umbilicus is not uncommon. The tissue is soft, vascular and granular, and dull red or pink, and may have a seropurulent secretion. Differentiation must be made from a *polyp*, a rare anomaly consisting of remnants of the omphalomesenteric duct. The tissue of the polyp is firm and resistant, and bright red, and has a mucoid secretion; it persists for years and is unaffected by astringents. Histologically, the polyp consists of intestinal tissue in contrast to the scar tissue of the granuloma.

The *treatment* is cauterization with silver nitrate, which should be repeated at intervals of several days until the base is completely dry.

## INFECTIONS OF THE UMBILICUS

Inflammation in the umbilical region, which may be caused by any of the pyogenic bacteria, is especially serious because of the danger of hematogenous spread or extension to the liver or peritoneum. The general manifestations may be minimal even when septicemia or hepatitis has resulted. Prevention of infection depends upon maintenance of a clean umbilical field. *Treatment* includes prompt antibacterial therapy and, if there is abscess formation, surgical incision and drainage.

## UMBILICAL HERNIA

Umbilical hernia is due to an imperfect closure or weakness of the umbilical ring and is often associated with diastasis recti. It is common in all races, but especially in the Negro. It appears as a soft swelling covered by skin which protrudes during crying or straining and can be reduced easily through the fibrous ring at the umbilicus. The hernia consists of omentum or portions of the small intestine. The size of the defect varies from less than a centimeter in diameter to as much as 5 cm., but large ones are rare. Most of the smaller ones disappear spontaneously during the first year or so of life.

Traditionally, umbilical hernias are kept "strapped" continuously during infancy from the time when the umbilical wound is epithelized, it being assumed that, if there is no tension on the umbilical ring, its margins will grow together. There is reason to doubt the effectiveness of the method for a hernia of any size, since the smallest ones close apparently irrespective of treatment, and the larger ones tend to persist. Until more adequate information is available, "strapping" of those of 1 or 2 cm. in diameter for six or seven months would seem justifiable. The hernia can be reduced by finger pressure and held in this position by drawing each side of the adjacent abdominal wall over it. A deep fold is thus formed and held by broad adhesive tape tightly applied. A coin or button should not be placed beneath the umbilical dressing, since it prohibits adequate approximation of the margins of the hernia. If the skin becomes irritated from the adhesive tape, the strapping should be discontinued temporarily until the skin heals. Application of tincture of benzoin to the skin affords protection against such irritation and ensures better

adherence of the tape. There are differences of opinion concerning the ideal age for surgical repair of the larger hernias and of the smaller ones that persist. For those of several centimeters in diameter there is no point in delay, and closure can be accomplished at any

age. For those of moderate size one may justifiably wait two or three years on the possibility that spontaneous closure might occur. In the female the eventual possibility of complications during pregnancy is an added reason for repair of the hernia during childhood.

## METABOLIC DISTURBANCES

The physiologic handicaps of the newborn infant in the maintenance of his water and electrolyte balance are discussed on page 290.

### TRANSITORY FEVER OF THE NEWBORN

Elevations of temperature ( $100^{\circ}$  to  $104^{\circ}$  F.) are occasionally noted on the second or third day of life in infants whose clinical course has been otherwise satisfactory. This disturbance has been termed "transitory fever of the newborn" and "dehydration fever." It is especially likely to occur in breast-fed infants whose intake of supplementary fluids such as glucose water or water has been particularly low or in infants exposed to high environmental temperatures, either in the nursery or in a bassinet near a radiator or in the sun. The lack of consistent relationship with the extent of weight loss or inadequacy of fluid intake may be a reflection of variation in initial stores of body water. The rise in temperature is associated with an increase in concentration of the serum protein; the fall, with an increase in plasma water. The rapid alleviation of symptoms by oral or parenteral fluids can leave no doubt as to the etiology.

The infant may be restless, and there may be a precipitous drop in weight. The urinary output and frequency of voiding diminish. The skin may show some loss of elasticity, and the fontanel may be depressed. The infant appears unhappy and takes fluids avidly. The usual apparent vigor of the infant is in contrast to the appearance of "being sick" in the presence of infection, although fever caused by infection may sometimes occur even earlier in the neonatal period, and at times without signs of prostration.

Oral administration of fluids leads to prompt reduction of the fever.

### EDEMA

Generalized edema occurs in association with the most severe forms of iso-immunization,

and varying degrees are seen in the offspring of diabetic mothers. Some premature infants may have considerable puffiness for no apparent reason. Edema of the face and scalp may result from pressure from the umbilical cord around the neck, and transient localized swellings of the hands or feet may similarly be due to intrauterine pressures. Edema may be present with heart failure due to congenital cardiac lesions; a lag in renal excretion of electrolytes and water may result in edema when there has been a sudden large increase in intake of electrolytes, particularly with feeding of concentrated mixtures of cow's milk. It is difficult to show a relation between low serum protein or low hemoglobin and the occurrence of edema in older premature infants, but occasionally the therapeutic response to plasma or blood transfusion is prompt. Rarely "*idiopathic hypoproteinemia*" with edema lasting weeks or months is observed in term infants. The etiology is unclear; and the disturbance is benign.

Scleredema is described on page 1278.

### TETANY

Tetany unrelated to a deficiency of vitamin D occurs occasionally in newborn infants, usually within the first week of life. The increased neuromuscular irritability stems from a decrease in serum calcium associated with an increase in serum phosphate (see p. 1110). The serum phosphatase is normal. Transient physiologic hypoparathyroidism, diminished ability of the neonatal kidney to excrete phosphate, and a high phosphate load from undiluted cow's milk formulas have all been considered contributory.

Irritability, muscular twitchings, tremors and convulsions are the symptoms. Laryngospasm and carpopedal spasm are less common. Since a positive Chvostek's sign is frequently observed in normal newborn infants, it cannot be interpreted as a sign of tetany of the newborn. The level of the serum calcium is regularly reduced below 7 or 8 mg. per 100 ml., and that of the serum phosphate is

elevated; an absolute diagnosis cannot be made in the absence of these chemical findings. The favorable response of symptoms to administration of calcium is not sufficient in itself to make the diagnosis, since calcium may act nonspecifically as a sedative. Furthermore, symptoms such as irritability and tremors may subside spontaneously, and convulsions resulting from cerebral edema, anoxia or injury may not be repeated during the neonatal period. The good prognosis of hypocalcemic convulsions and the guarded to poor prognosis for convulsions of other causes in the newborn period make establishment of the diagnosis by chemical examination of the blood desirable. When there is associated

albuminuria, pyuria and/or a persistently high blood urea not associated with dehydration, urologic studies are indicated.

The response to calcium therapy is dramatic, convulsions being controlled by the intravenous administration of 5 to 10 cc. of calcium gluconate in 10 per cent solution. Intramuscular injection of calcium is contraindicated because local induration and necrosis may occur. Calcium should be given orally for approximately a week, preferably as calcium chloride (1.0 gm.) or calcium lactate (2 to 3 gm. a day) in 10 per cent solution. The use of parathyroid extract or of dihydrotachysterol is not indicated; vitamin D is not effective.

## DISTURBANCES OF THE ENDOCRINE SYSTEM

Details of diagnosis and management of the endocrinopathies are covered in the section on The Endocrine System. The purpose of this section is merely to call attention to those endocrine disturbances which may be identified at birth or during the first month of life.

*Pituitary* dwarfism is usually inapparent at birth, the infant being of normal size. Conversely, constitutional dwarfs usually demonstrate length and weight consistent with prematurity, but are born after a normal gestational period and have the physical appearance of infants born at term.

*Thyroid* deficiency may be apparent at birth in genetically determined cretinism or in infants of mothers treated with thiouracil or its derivatives during pregnancy. Constipation, prolonged jaundice, lethargy or poor peripheral circulation as manifested by persistently mottled skin or cold extremities should always rouse suspicion of *cretinism*. Temporary hyperthyroidism may be seen at birth in the infants of mothers with hyperthyroidism or of those who have been on thyroid medication.

Transient *hypoparathyroidism* may be manifest as tetany of the newborn (p. 342).

The *adrenal gland* is subject to numerous disturbances which may be manifest and require lifesaving treatment during the newborn period. Acute adrenal *hemorrhage* and failure may be seen after breech or other traumatic deliveries or in association with overwhelming infection. Phallic or clitoral

enlargement apparent at or soon after birth may be the clue to *adrenal cortical hyperplasia*. Signs of deficiency of salt and water hormone with vomiting, diarrhea, dehydration, convulsions or shock may be present. Since the condition is genetically determined, newborn siblings of patients with adrenal cortical hyperplasia who are salt-losers should be observed closely for manifestations of adrenal insufficiency. *Congenitally hypoplastic adrenal glands* may also give rise to adrenal insufficiency during the first few weeks of life.

Anomalies of the *gonads* may be apparent at birth. Of particular interest is gonadal dysgenesis (Turner's syndrome, Bonnevie-Ullrich syndrome, ovarian agenesis). Female infants with webbing of the neck, lymphangiectatic edema, hypoplasia of the nipples, cutis laxa, low hairline at the nape of the neck, deep-set ears, high-arched palate, deformities of the nails, cubitus valgus and other anomalies should be suspected of having gonadal dysgenesis. Approximately 80 per cent of these apparent females have a male chromosomal sex pattern.

Transient *diabetes mellitus* of unknown etiology is occasionally and only seen in the newborn. It usually presents as dehydration, loss of weight, or acidosis. Hypoglycemic convulsions may occur during the first few days of life in the infants of diabetic mothers, and children with so-called idiopathic hypoglycemia may have the onset of symptoms during the neonatal period.

## INFECTIONS OF THE NEWBORN

The reader is referred to other sections for discussion of specific diseases which may be particularly important in the newborn infant. See, in particular, Syphilis, Tetanus, Cytomegalic Inclusion Disease, Toxoplasmosis.

Infections of the newborn infant may be caused by any pathogenic bacterial or viral agent. He is more susceptible, however, to organisms which are usually nonpathogenic for older children and for adults outside of the geriatric age group, in whom such infections are again seen with relatively greater frequency. The *Pneumococcus*, beta-hemolytic streptococcus, and *H. influenzae*, common pathogenic agents in later infancy, are relatively uncommon causes of infection in the first few weeks of life. At this time coliform organisms and *Staphylococcus aureus* are the most frequent causes of severe infections; other relatively common bacterial pathogens are enterococci, *Klebsiella*, *Pseudomonas*, *Proteus* and *Salmonella*. Nursery epidemics caused by any organism with antibiotic susceptibility are probably best managed by routine administration for several weeks of an appropriate antibiotic to every infant in the nursery in a manner similar to that to be described for the prevention of epidemics of staphylococcal infection.

The most frequent serious infections of the newborn are pneumonia, septicemia, diarrhea, meningitis and peritonitis. Of these, pneumonia and septicemia are common; diarrhea has become relatively uncommon in the United States, but has a high incidence in individual epidemics; meningitis is present in approximately 25 per cent of cases of septicemia; and peritonitis is rare as a well developed clinical syndrome, presumably because of the effectiveness of modern chemotherapy against the beta-hemolytic *Streptococcus* and against the spread of blood-borne infection to the peritoneal cavity.

In pneumonia, septicemia and meningitis the prognosis is heavily influenced by early diagnosis and institution of specific treatment with appropriate antibacterial agents. All three are distinguished by their lack of specific signs or symptoms in the early stages (see Clinical Manifestations of Disease in the Newborn, p. 314, and of pneumonia on p. 326). In the absence of dehydration or high environmental temperature they are the

commonest causes of body temperatures over 100° F. in the newborn infant. Frequently, however, there is no elevation of temperature, or the temperature may be subnormal, and failure to feed well, lethargy, irritability, vomiting or episodes of cyanosis may be the only evidence of any one of these major infections. Icterus after the second or third day of life is especially suggestive of septicemia. The classic signs of meningitis in the small infant (bulging fontanel, high-pitched cry, vomiting and convulsions) are late signs, and the diagnosis must be made before they appear in order to reduce the mortality and morbidity of the disease. Acute meningitis caused by gram-negative bacilli, in particular, frequently becomes chronic, with a high incidence of permanent residuals. Timely diagnosis of pneumonia, septicemia and meningitis depends on the use of liberal indications for securing a roentgenogram of the chest and a blood culture and for performing a spinal puncture in infants who "are not doing well." Premature infants are especially prone to serious infections with few or no clinical manifestations.

### ESCHERICHIA COLI INFECTIONS

The commonest *etiologic agent* of all serious infections (pneumonia, septicemia, meningitis and diarrhea) of the newborn is *E. coli*. Ten serologic types of this organism have been linked to individual epidemics of diarrhea of the newborn, types 0111:B4, 055:B5, 026:B6 and 0127:B8 being the most common. The relation of these particular strains of *E. coli* to infections other than diarrhea has not been clearly defined; they have not been shown to produce epidemic disease other than diarrhea.

Systemic infections caused by *E. coli* are best treated with chloramphenicol, tetracycline or streptomycin. Initial resistance of the organism is least likely with chloramphenicol, but may develop with it or any available antibiotics. In intestinal infections neomycin is the drug of choice (see p. 221).

### STAPHYLOCOCCAL INFECTIONS

Second in frequency to *E. coli* as a cause of infection in the newborn, *Staphylococcus*

*aureus* has assumed relatively greater importance in recent years, owing to the frequent occurrence of epidemic nursery infections with strains resistant to most of the commonly used antibacterial agents.

Although staphylococcal pneumonia, septicemia or enteritis may occur without warning in the newborn infant, each is usually preceded by apparent skin infections of the infant or of contacts which may consist of small pustules or furuncles, or of large furuncles, cellulitis, bullous impetigo or breast abscess. Retro-orbital abscess complicating osteomyelitis of the maxilla, presumably as the result of infection entering through an abrasion of the upper gum, has received recent attention. Osteomyelitis elsewhere and meningitis are relatively frequent complications of septicemia. Staphylococcal meningitis without bacteremia suggests the presence of a communication (dermal sinus) between the skin and the subarachnoid space. A leaking meningocele is an obvious portal of entry. The umbilicus, a circumcision wound or other surgical incision may serve as a route for staphylococci to reach the blood stream, as may any abrasion of the skin.

Nursery epidemics of staphylococcal infection usually begin with increasingly frequent appearance of small pustules. More severe infections of the skin, septicemia or enteritis are usually seen next. Although the initial infection is acquired in the nursery, these and other serious manifestations may not make their appearance for weeks or even months after the baby has been discharged. Therefore the existence of an epidemic of major proportions may not be suspected unless the infants are followed up carefully after discharge and unless all cases of furuncles, breast abscess, pneumonia and other less frequent staphylococcal infections during the first months of life are reported to the nursery where the patients were born. A high incidence of small pustules may be the only evidence in the nursery of an epidemic which is resulting in major staphylococcal infections among 15 to 20 per cent of discharged infants and among other members of their families.

Recent investigations suggest that epidemics are due to certain strains of hemolytic *Staphylococcus aureus* which appear to be of particular pathogenicity. One such strain (phage type 42B, 47C, 44A, 52, 80, 81) was shown to be the causative organism of nineteen epidemics throughout the world in

1954–1956. The pathogen is undoubtedly introduced initially into the nursery by personnel or by an infant who acquires it from his mother during the periods of contact with her. Once the organism has been introduced, the infants in the nursery, as well as adult carriers, constitute the reservoir of infection and spread it from baby to baby. Anatomic areas of the infant which constitute particular reservoirs are the skin, the anterior nares and the umbilical cord stump.

**Prevention.** All persons with skin infections should be excluded from the nursery and from contact with the infant after discharge. Mothers with staphylococcal infections should be isolated and treated while their infants remain in the nursery out of contact with them. Use of soap or detergent containing hexachlorophene tends to reduce the bacterial population on the skins of nursery personnel. The latter should also be specifically instructed that the anterior nares constitute the chief reservoir in carriers. Initial and daily bathing of the infants with a soap or detergent containing hexachlorophene reduces the incidence of skin infection, but not of infection of the anterior nares. Daily painting of the umbilical cord stump with bactericidal dyes reduces the incidence of nasal and skin colonization of staphylococci, provided all infants in the nursery are so treated. Avoidance of overcrowding in the nursery is important. Once an epidemic is started, the usual measures of prompt isolation of new cases, tightening up on all nursery techniques, scrubbing the nursery and its contents, and changing the location of the nursery are usually of little avail. On the other hand, the exclusion of personnel who are carriers of the pathogenic strain, and routine oral administration of chloramphenicol or erythromycin in dosage of approximately 50 mg. per kilogram per twenty-four hours in divided doses to each infant from the day of admission through the day of discharge usually results in prompt disappearance of the epidemic. Maintenance of this regimen for three weeks ordinarily is sufficient to control the epidemic.

**Treatment.** The treatment of staphylococcal infections is best accomplished by systemic administration of an antibiotic effective against the particular organism involved. Chloramphenicol, erythromycin or novobiocin in that order are the drugs of choice. The tetracyclines, penicillin, streptomycin and the sulfonamides are ineffective against a high

percentage of pathogenic staphylococci, and no drug is effective against more than 85 to 95 per cent of strains. Therefore tests of antibiotic sensitivity in vitro should always be done and the medication changed accordingly if the drug being used is not producing a satisfactory clinical response. In the presence of an obviously good clinical response, a shift of medication on the basis of the results of sensitivity tests in vitro should be questioned. As noted on page 325, the broad-spectrum antibiotics are less well absorbed from the intramuscular spaces than are penicillin and streptomycin, and they require more fluid (about 1 cc. per milligram of drug) for absorption from the intestine than does penicillin.

In addition to systemic therapy, bathing with soaps or detergents containing hexachlorophene and the local application of bacitracin ointment will aid in eradicating skin lesions. Accumulations of pus, wherever encountered, should be drained surgically.

## DIARRHEA IN THE NEWBORN

Traditionally a scourge of all nurseries because of its great contagiousness and high morbidity and mortality rates, epidemic diarrhea of the newborn is now a relatively infrequent but still serious problem in the United States. *Etiologically*, it is not an entity. A number of bacterial and viral agents have been identified as the causative or probable causative agents in individual epidemics. With the possible exception of pathogenic strains of *E. coli* and occasional viruses causing respiratory or oral infections in adults, they do not differ significantly from the usual etiologic agents of diarrhea (p. 655). On the basis of present evidence it would appear that certain types of *E. coli* (p. 344) are responsible for a high percentage of nursery epidemics of diarrheal disease. The specificity and severity of the disease are related principally to the host factors of low immunity, small metabolic reserve of water and electrolytes, and poorly developed homeostatic mechanisms. The universal presence of a large, changing, crowded and susceptible population in almost any newborn nursery is also an ideal environmental situation for any contagious disease to become epidemic. Premature or debilitated infants are especially susceptible. Sporadic cases are also seen; they usually occur in the home after exposure to an older sibling or adult with an enteric infection.

**Clinical Manifestations.** The incubation period is most commonly one to three days. At onset the infant usually becomes listless or fretful, nurses less well than usual, fails to gain or may actually lose weight. Vomiting is an inconstant symptom, as is abdominal distention. The temperature is usually normal, but may rise to 100° to 104° F. When the diarrhea starts, the stools tend to be watery, yellowish (later greenish) and acid enough to produce irritation of the skin of the buttocks within a few hours. They are usually frequent and passed explosively. On the other hand, an occasional infant may go into shock and die from water and electrolyte loss into the intestinal lumen before a diarrheal stool is passed. Mucus, pus and macroscopic blood are commonly absent, although in southern Europe a highly fatal form of diarrhea of the newborn characterized by the passage of copious amounts of green mucus is seen. As the diarrhea progresses the infant becomes increasingly restless with a frequent short and feeble cry. With progressive dehydration, thirst may give way to refusal to feed, and the infant becomes drowsy and, finally, comatose. In the final stages of dehydration the infant's face resembles that of a mummy, the eyes are deep-sunken, the skin takes on a grayish cast, and there is circumoral cyanosis and an apparent state of shock. Hyperpnea is frequently absent in spite of acidosis with carbon dioxide levels as low as 2 mEq. per liter. There is hemoconcentration, and protein, white cells and casts are found in the urine in considerable quantities. As in most diseases, the severity and the presence or absence of the various clinical manifestations vary greatly from patient to patient.

The clinical course varies from a few days to several weeks. Relapses or exacerbations are common. Complications include otitis media, bronchopneumonia, bacteremia, peritonitis from perforation of an intestinal ulcer, and renal vein and cerebral sinus thrombosis.

**Prevention.** The hospital nursery technique should be designed to eliminate chances of infection or cross infection among the infants. This involves adequate floor area to avoid overcrowding, complete individual bassinets and equipment for each infant, careful supervision of the preparation of formulas, and well-trained, conscientious personnel who are numerically adequate.

Any direct or indirect contact with persons with intestinal disease or direct contact with

any with respiratory infections must be avoided. This means the exclusion from the nursery of all personnel who have had even mild diarrhea or vomiting within forty-eight to seventy-two hours, and of all personnel having more than the most fleeting contact with active cases of diarrhea either professionally or at home. In nurseries a high index of suspicion must be maintained, especially since the onset of an epidemic may be so insidious that the possibility is not considered until several infants have diarrhea. A frequent cause of this situation is the discharge from the nursery of the initial case or cases before definite signs of the disease have appeared, but after the contagious state is already present. Therefore it is essential that the development of diarrhea in an infant after discharge be reported immediately to the person in charge of the newborn nursery. Immediate reporting to local or state health officials is equally important.

Nursery personnel must be constantly on the alert for abnormal stools among their charges. Differentiation must be made between diarrhea and the loose and frequent movements characteristic of transitional stools. The breast-fed infant may have more frequent and more liquid stools than the bottle-fed infant, and may be affected by the dietary or medicinal intake of his mother. Overfeeding, high carbohydrate content of the formula, intestinal intolerance to cow's milk or the use of soybean or protein hydrolysate formulas may be responsible for loose stools in the bottle-fed infant. Aganglionic megacolon may be manifest initially in the newborn as diarrhea. Once a baby in a nursery for newborns is identified as having diarrhea he should be isolated in a separate nursery and cared for by personnel who do not have contact with the remaining infants. The latter and those discharged from the exposed nursery must be watched closely for any untoward signs. New infants should not be admitted to the nursery from the time of recognition of the second case until it has been cleared of its current population. It should then be thoroughly scrubbed and aired before admissions are resumed.

**Prognosis.** The average fatality rate in epidemics of recent years has been about 40 per cent. With presently available treatment it should be lower, and in a few epidemics all affected infants have survived. The subsequent course of surviving infants is, in general, uneventful, although chronic in-

testinal disturbances are an uncommon sequel.

**Treatment.** Except for those epidemics due to bacteria against which effective specific antibacterial agents are available, treatment is symptomatic and supportive. It does not differ from that of diarrheal disturbances in later infancy (pp. 187 and 189). Neomycin is the only antibiotic which has been found effective in breaking a nursery epidemic due to the specific serologic types of *E. coli* which have been shown to be pathogenic. For this reason it is recommended that 50 mg. of neomycin per kilogram of body weight per day be administered orally in divided doses to all infants in the nursery up to the time of discharge of the last infant present at the time the medication is started. Nursery personnel should also be cultured, since they may be asymptomatic carriers of pathogenic strains of *E. coli*. Any carriers discovered should be relieved of duty and treated with neomycin until the organism has been eradicated from their intestinal tracts.

## NEONATAL INFECTION DUE TO

### LISTERIA MONOCYTOGENES

Of the human infections caused by *Listeria monocytogenes*, that of purulent meningitis is the one most commonly recognized (p. 424), but a generalized *miliary granulomatosis* in stillborn fetuses and newborn infants is unique. The incidence is not known, probably because the infection is most often not identified; in one rather large series *L. monocytogenes* was responsible for 2 per cent of neonatal deaths.

The fetus is apparently infected transplacentally and usually dies before birth. In those born alive manifestations may be apparent from the time of birth or may be delayed a week or so. The clinical pattern is not characteristic. There is often brownish discoloration of the amniotic fluid. When the onset is shortly after birth, the principal signs are those of cardiorespiratory distress. Diarrhea and vomiting are common. When the onset is delayed, it may be gradual, but the course is progressive and is usually characterized by bronchopneumonia. Meningitis is not uncommon. Granulomas appearing as dark red or livid papules may be present on the oropharynx and the skin.

Pathologically there are microscopic to pinhead-sized nodules in many organs, viz.,

liver, spleen, adrenals, lungs, pharynx, gastrointestinal tract, brain and meninges and skin.

The diagnosis is established by identification of the organism in the urine or blood of the infant, and suggested by similar identifications in the mother. High agglutinative titers may be observed for a short time after the infection.

Most of the available antibiotic agents are effective against *L. monocytogenes*; penicillin is probably the agent of choice.

## COXSACKIE VIRUS INFECTION IN THE NEWBORN

An acute fulminating febrile illness may result from infection of newborn infants with Coxsackie virus, group B. It may be associated with minor respiratory or other infection in the mother shortly before delivery or may occur in apparently epidemic form in the nursery. At autopsy the characteristic finding is diffuse myocarditis, and other organs may be involved (see p. 529).

## HERPES SIMPLEX OF THE NEWBORN INFANT

Severe generalized infection of the newborn infant may be caused by the virus of herpes simplex (see p. 493).

# Unexpected Sudden Death

Unexpected deaths include those which occur after a brief and apparently mild illness and sudden deaths which occur in seemingly healthy infants and children. Death may occur suddenly in many of the diseases of infancy and childhood, e.g., in diphtheria, but in such instances it cannot be considered entirely unexpected. The discussion here is limited to unexpected death for which there is no adequate clinical explanation. Such deaths are most likely to occur during the first six months of life and only rarely after the first year.

Careful postmortem studies, including histologic, bacteriologic and chemical investigations, will provide the explanation for such unexpected deaths in the majority of instances. In a few patients, however, even the most careful studies will fail to reveal an adequate cause of death; although it has been suggested that death results from overwhelming infections before morphologic changes are apparent, in the absence of positive bacteriologic studies the evidence for this is inconclusive.

**Acute Infection.** Infections of various types are the leading cause of sudden death in infants. In some instances death is preceded by a minor illness of brief duration such as a mild upper respiratory tract infection. Sometimes, however, death from an acute infection occurs suddenly with no apparent preceding illness. Postmortem examination of infants dying suddenly may reveal few or no significant macroscopic or microscopic evidences of an inflammatory process, yet culture of the heart's blood may yield virulent organisms such as pneumococci, meningococci, beta-hemolytic streptococci or *Hemophilus influenzae*. In such instances death may justifiably be attributed to an overwhelming infection which has progressed with such rapidity as to preclude the production of morphologic changes. However, the actual mechanism responsible for such deaths is not established; earlier studies suggesting the presence of hypogammaglobulinemia in these

infants have not been confirmed. The interpretation of postmortem blood cultures which contain such organisms as *Proteus*, *Pseudomonas*, *Escherichia coli* or even staphylococci is often difficult. In general, in the absence of other evidences of infection by these organisms their presence is attributed to agonal invasion of the blood stream and is not considered a cause of death.

In other instances of sudden death inflammatory processes such as pneumonia or meningitis may be demonstrable macroscopically or by histologic study at the time of autopsy. Meningococcemia and, somewhat less characteristically, septicemia associated with other organisms such as *H. influenzae* or pneumococci may proceed with terrifying rapidity to death. At postmortem examination a petechial or purpuric rash may be associated with varying degrees of bilateral adrenal hemorrhage (Waterhouse-Friderichsen syndrome); in some instances a similar clinical pattern is associated with extensive cytolytic changes in the adrenal cortices (Rich) in the absence of hemorrhage. Cerebral abscess, especially in infants, may be associated with few clinical manifestations until death occurs unexpectedly after rupture of the abscess into the ventricular cavity.

**Congenital Malformations.** Unrecognized congenital cardiac malformations are occasionally responsible for unexpected death, and patients with known cardiac malformations, e.g., aortic stenosis, may die suddenly and unexpectedly. In addition, infants with endocardial sclerosis, anomalous origin of the left coronary artery, medial necrosis of the coronary arteries, and possibly those with glycogen storage disease of the heart, congenital rhabdomyomas or hamartomas of the myocardium, may die suddenly in the absence of any known pre-existing cardiac disease. Somewhat more frequently, however, the unexpected death of these infants is preceded by a brief period of respiratory distress suggestive of a pulmonary inflammatory process. Acute myocarditis (see p. 529), which may

closely simulate the aforementioned diseases, may be responsible for sudden death in an apparently healthy infant or even in an older child; occasionally it is responsible for sudden death in the neonatal period.

Patients with severe malformations of the central nervous system, known to have been present since birth or shortly thereafter, may die suddenly and unexpectedly. At autopsy little of significance may be found except for the lesions of the central nervous system. The explanation for these sudden deaths is not apparent, but it seems possible that infants and children with severe damage to the central nervous system may die as a result of relatively minor illnesses which would not be fatal to a normal child.

**Hemorrhage.** Hemorrhage into various sites, especially into the brain or abdominal cavity, may result in sudden unexpected death. In intracranial hemorrhage, such as may occur with rupture of an aneurysm of the circle of Willis, signs and symptoms referable to the central nervous system are usually apparent for at least a brief period prior to death. Small premature infants may die early in the neonatal period after only a few hours of distress as a result of rupture of a subependymal hemorrhage into the lateral ventricle. Massive intracranial hemorrhage with unexpected death may be the first apparent manifestation of acute leukemia in children. Rupture of a subcapsular hematoma of the liver in a newborn infant may be responsible for unexpected death, as may intraperitoneal hemorrhage following rupture of the liver or, less frequently, of the spleen.

**Asphyxia.** Aspiration of foreign bodies may cause complete obstruction of the larynx or trachea with resultant sudden unexpected death. The parents may be unaware of the aspiration, which is demonstrated only at necropsy. Aspirated gastric contents are often encountered in the tracheas of infants and children dying of a variety of causes; in the absence of definite evidence of obstruction, as by a bolus of food lodged in the larynx, such aspiration should not be considered a primary cause of death.

**Poisoning.** Poisoning of various types may be responsible for unexpected death, but clinical manifestations of illness are usually present for at least a brief period prior to death. No history of ingestion of poison may be elicited, since the family may be unaware of its occurrence.

**Miscellaneous Causes.** Emery has reported sudden deaths in infants associated with

multiple pulmonary thromboses. Unexpected death has occurred as a result of heat prostration in patients with fibrocystic disease of the pancreas in whom clinical manifestations of the disease were not apparent.

Although sudden unexplained deaths frequently have been attributed to *suffocation* by pillows or bedclothes, substantial evidence of such an occurrence is difficult or impossible to obtain. In the absence of an unequivocal history of suffocation, as in homicide or strangulation, death should not be attributed to this cause. Even in the absence of significant lesions following complete post-mortem examination the diagnosis of suffocation should not be made simply because an infant is found dead face down in bed. In the absence of irrefutable evidence to the contrary, the family should be made to understand that they were in no manner responsible for the death of their child.

The rapidity with which thymic involution may occur in association with a variety of illnesses is often not appreciated, nor is the relatively large size of the lymph nodes (especially those in the mesentery) and lymphoid aggregates which are encountered in children. As a result, the relatively large thymus and prominent lymphoid aggregates which are commonly observed in infants and children dying suddenly while in apparent good health, or following anesthesia, minimal infections or other trivial causes, have led to the erroneous concept of status thymicolymphaticus. These so-called thymic deaths have been attributed to a variety of vague and unproved causes, but since there is no conclusive evidence that the thymus per se is in any way responsible for these deaths, the term "status thymicolymphaticus" might better be omitted from medical literature.

# Nutritional Disturbances

## MALNUTRITION

The term "malnutrition" is commonly used to indicate a state of undernutrition rather than a disturbance of the process of nutrition, which is implied in its strict interpretation. The use of the term is further restricted to identify the general clinical manifestations of undernutrition rather than specific disturbances, e.g., rickets or scurvy, which result from lack of single essential nutrients. Malnutrition should be considered a secondary and not a primary diagnosis, and an effort should always be made to identify the underlying causative factor.

The evaluation of nutritional status is far from being adequately defined. Severe disturbances are readily apparent, but mild disturbances may be missed, not only by careful physical examination, but also by laboratory methods now available. Evaluation of nutritional status merely by some arbitrarily determined percentile deviation from average weight values for height and age is not satisfactory. It not only identifies certain naturally small but healthy children as being undernourished, but also fails to detect a larger group whose nutritional status is inadequate, although their weight is within the range of average for their height and age. The rate at which growth is progressing is a more reliable index of nutritional status and is one of the screening methods for separating from a large group those children who should be more thoroughly studied for the presence of possible defects.

Dietary surveys, when carefully carried out, provide means for identifying groups and even individuals in whom malnutrition may exist. In view of the recognized inaccuracies in obtaining a history of dietary habits, a record of the child's daily intake for a week or so is recommended. For this purpose the type of record illustrated in Table 26 (p. 134) may be used.

Measurements of blood constituents by microchemical procedures is another means of assaying the nutritional status of large

groups of persons. Methods are available for the determination of several vitamin levels (A, C and thiamine), blood and serum iron, and serum protein on 0.1 ml. of blood serum, which provide a screening method for selection of persons with manifest or potential nutritional deficiencies. *Low blood levels of the various vitamins cannot be interpreted as evidences, per se, of nutritional disturbances, since physical changes resulting from the various vitamin deficiencies require some time for their development.*

## MALNUTRITION IN INFANTS

Severe malnutrition in infants, variously termed "infantile atrophy," "inanition," "marasmus," and "athrepsia," is observed much less frequently in the United States than formerly, but is prevalent in certain parts of the world. This decrease in incidence probably represents improvement in the artificial feeding of infants and to some extent also reflects a lower incidence of severe gastrointestinal disorders and of syphilis and tuberculosis among infants.

**Etiology.** Severe malnutrition may result from an inadequate caloric intake, either because of insufficiency of the diet or because of improper feeding habits, including those of disturbed parent-child relationships. Malnutrition may also result from improperly balanced diets, from chronic disease responsible for anorexia, for deficient digestion and assimilation, for vomiting or for diarrhea, and from congenital malformations, such as cleft palate, cardiac abnormalities and congenital dilatation of the colon. Extreme malnutrition may occur in infants with cerebral damage.

**Clinical Manifestations.** The most common manifestation is failure to gain weight, followed by progressive loss of weight until emaciation results. Fat is retained in the sucking pads of the cheeks longer than in other parts of the body, and until wasting is extreme the extent of malnutrition may be missed unless the baby's body is exposed. When the loss of subcutaneous tissue is

marked, the skin loses turgor and is wrinkled over the entire body; when the fat pads in the cheeks disappear, the infant is likely to assume the appearance of a withered old man. The abdomen may be distended or may be sunken and reveal the outlines of the intestines. The muscles are usually flabby and relaxed, but there may be hypertonia sufficient to produce arching of the back and retraction of the head. A spinal puncture may be required to eliminate the possibility of meningitis. The temperature is usually subnormal, the pulse may be slow, and the basal metabolism tends to be reduced. At first the infant may be fretful, but later he becomes listless. The appetite is likely to be diminished in the later stages of inanition. There is usually constipation, but there may be so-called starvation diarrhea, and the stools may contain much mucus.

Ketonuria is common in the early stage of inanition, but frequently disappears in the later stages. Severe hypochromic anemia is almost a constant finding. Plasma protein is usually lowered, although in the presence of hemoconcentration the serum level may approximate the normal range. Glucose tolerance curves may be diabetic in type; this pattern disappears when the nutritional state is improved. There may be a positive tourniquet test for increased capillary fragility, and in some instances there is spontaneous purpura. There may also be evidences of specific deficiencies such as rickets, scurvy, beriberi, ariboflavinosis, pellagra and keratomalacia. Nutritional edema is not unusual.

Intercurrent infections are common, especially of the gastrointestinal, respiratory and urinary tracts. Oral thrush, after the newborn period, occurs almost exclusively in malnourished infants, as do atrophic ulcers over areas of pressure from bony prominences. The higher mortality from infections among infants of the lower socio-economic group may be attributed in part to nutritional deficits.

**Diagnosis.** The diagnosis of malnutrition is made from the appearance of the child, but every effort should be made to determine the cause. It will require a careful history of dietary and feeding habits and of illness and a thorough physical examination in the search for any primary or secondary disorder.

**Prevention.** Prophylactic measures are of the greatest importance and include adequate feeding, appropriate parent-child relationship, good physical hygiene, immunization against the preventable infections, and

early diagnosis and treatment of acquired infections.

**Treatment.** Any coexistent physical disturbance which is remediable should receive appropriate therapy. Initial feedings should be low in quantity and in caloric value; too rapid increase in dietary intake may result in severe digestive disturbances with vomiting and diarrhea. Half-strength skimmed lactic acid milk to which about 2 per cent sugar is added is a satisfactory starting formula. Increases in carbohydrate and protein are then made within the limits of the infant's capacity when there is no vomiting or diarrhea. Within a relatively few days the diet can be increased to full strength (nonlactic acid) milk. Caloric requirements may need to be higher than indicated by the infant's weight, and may be as much as 50 per cent greater before significant gains in weight are attained. Intramuscular injections of crude liver extracts at intervals of two or three days for several weeks may be helpful. Vitamins B and C should be supplied in amounts equal to four or five times the usual daily requirements during the first week or two, and vitamins A and D in usual amounts.

Parenteral administration of fluid may be necessary initially to correct dehydration and to establish renal function (p. 186). When continuous intravenous feeding is necessary, amino acids should be included in amounts equal to 1.5 to 2 gm. per pound (3 to 4 gm. per kilogram) of body weight daily.

Hospitalization should be limited to the stage when parenteral therapy is necessary and rarely until feeding habits are established.

#### MALNUTRITION IN CHILDREN BEYOND INFANCY

**Etiology.** Malnutrition in children more than two years of age may be a continuation of an undernourished state begun in infancy, or it may stem from factors which become operative at any time during childhood. In general, the causes are the same as those responsible for malnutrition in infants. When poor dietary habits are associated with a generally poor hygienic situation, with finical eating habits of other members of the family, with disturbed parent-child relationships, especially overanxiety concerning eating habits, or with chronic disease, the problem is complex.

Under the age of five or six years poor eating habits can often be traced directly to

parental factors, of which overconcern about the quantity or the quality of the diet is the principal one. In children of all ages inadequate rest, both from the standpoint of insufficient sleep and from too much emotional excitement, such as that associated with the movies, radio and television, is an important factor. In older children schoolwork and social activities may interfere with securing adequate rest. School-age children are also likely to develop inadequate eating habits, especially at breakfast and lunch, because sufficient time is not allotted or, at lunch, because the meal may be poorly balanced. During adolescence girls frequently restrict their dietary intake for esthetic reasons. Random between-meal eating, especially of such items as candy, ice cream and malted milks, is likely to reduce the appetite at mealtime.

**Clinical Manifestations.** Malnutrition does not invariably result in underweight. Fatigue, lassitude, restlessness and nervousness are frequent manifestations. Restlessness and overactivity are frequently misinterpreted by parents as evidences of lack of fatigue. Anorexia, easily induced digestive disturbances and constipation are common complaints, and even in older children the starvation type of mucoid diarrheal stool may be observed. Malnourished children often have a limited span of attention and do poorly in their school work. There is an increased susceptibility to infections, especially to those of the gastrointestinal and respiratory tracts. Muscular development is inadequate, and the poor tone of the flabby muscles results in the so-called fatigue posture with rounded shoulders, flat chest and protuberant abdomen. Such children often have expressions of fatigue: the face is pale, the complexion is "muddy," and the eyes lack luster. Hypochromic anemia is common. In protracted cases there may be delayed epiphyseal development, irregularities in dentition, and delayed puberty.

The appraisal should always include a careful history of dietary habits, physical hygiene and illness, a thorough physical examination, and the necessary laboratory examinations to establish, whenever possible, the cause or causes.

**Treatment.** There is a great need for individualization, with treatment directed at correction of the underlying psychologic and physical disturbances. An adequate diet (p. 111) should be outlined; vitamin concentrates may be added and continued for a time after the dietary intake has been ade-

quate. When anorexia is a problem, the essential items of the diet should be provided in as concentrated a form as possible, and the fat content should be low. Between-meal snacks need not be prohibited if they do not interfere with the appetite for the next meal, but milk and candy should be eliminated at such times and fruit or fruit juices provided. When the family eating habits are unsatisfactory, attempts should be made to correct them.

Bedtime should be sufficiently early to ensure a full night's sleep, and, if possible, there should be a nap during the daytime. Short rest or quiet periods of fifteen to twenty minutes before meals may abolish the tension which at times interferes with the appetite. Exciting stories, movies, radio and television should be avoided before bedtime, especially when there is difficulty in going to sleep. Reasonable regularity in habits without regimentation should be encouraged. Out-of-door activity is to be encouraged in sedentary children and group play for those who tend to be seclusive. Every attempt should be made, however, to permit the child to develop natural interests. In some instances the assistance of a child guidance clinic may be helpful.

## OBESEITY

Obesity is relatively common during the latter part of childhood and during adolescence. There is no exact line of demarcation between normal nutrition and overnutrition; practically, the diagnosis is made from the appearance of the child rather than from an arbitrary excess in weight. Children of the stocky type may have relatively large skeletal frames and more than the average amount of muscular tissue, so that their weight and height as well as their appearance of bigness exceed that of the average child of their age, but they are not to be considered obese. Obesity or overnutrition is simply a generalized excessive accumulation of fatty subcutaneous tissue.

Despite the fact that medical attention has been focused on obesity in the preadolescent male, Bruch's extensive studies have shown that obesity occurs with equal frequency in both sexes. Severe obesity is less common among the wealthier classes than among the poor, and more frequent in immigrant families.

**Etiology.** The principal causes are heredity, overeating, emotional or psychologic diffi-

culties, endocrine disturbances and central nervous system disorders. If one eliminates the obesity associated with hypothyroidism and with the rare instances of true Froehlich's syndrome, hypogonadism and certain adrenal cortical tumors, excessive food intake appears to be the factor mainly responsible for obesity. The reasons for the excessive intake of food, however, may differ, and adequate therapy is possible only when the underlying cause is understood.

Though the theory of a simple direct relation between caloric intake and energy output has much to commend it, the possibility of endogenous differences between persons who are naturally thin and those who are naturally obese which determine their physical activity and their appetite cannot be lightly dismissed. The two principal arguments presented in support of the endogenous theory are based on inheritance and on imbalance of the endocrine glands.

Many instances of so-called idiopathic hereditary obesity are simply reflections of familial dietary habits. Perhaps the strongest evidence in favor of a hereditary tendency to obesity is the demonstration of it in breeding experiments in mice. Supportive human data are not available.

The relation between endocrine disturbances and obesity is not clear.

Obesity has frequently been attributed to the residuals of encephalitis, possibly in the hypothalamic area. However, Greene points out that in his series loss of weight occurred approximately five times as often as did gain in weight after encephalitis. In view of the inability to assess the role of a possible anatomic residual, it would seem wise to attempt to evaluate the effects of the encephalitis on physical activity and emotional status in the individual child in order to plan his therapy as effectively as possible. Lesions of the brain in the hypothalamic region have been assumed to be etiologic factors in the production of obesity. Experiments with rats in which obesity regularly developed after the production of hypothalamic lesions are cited in support of this theory. Similar lesions in monkeys, however, do not result in obesity, so that the results of animal experimentation cannot be directly applied to human beings.

In 1901 Froehlich published a case report of a boy with a tumor at the base of the brain who presented a picture of obesity accompanied by physical and sexual infantilism. Since then the term "Froehlich's syndrome" has been loosely applied, and numerous

preadolescent obese males have been erroneously labelled with this diagnosis (see p. 1162).

Bruch believes that emotional disturbances constitute the principal cause of obesity in late childhood and adolescence. The withdrawn, unhappy child may develop an excessive appetite in his attempt to escape from a difficult environment. Though the food intake should be limited, complete therapy must of necessity include a careful search for emotional factors, and their correction if possible.

**Clinical Manifestations.** Obesity may become evident at any age from birth on, but makes its appearance in children most frequently in late childhood or in the prepuberal period, and is often designated as *obesity of adolescence*. There is no constant physical pattern of these children, many of whom are not only heavier than their cohorts, but are also taller, and their skeletal structures are generally larger. The facial features often appear disproportionately fine, the nose and mouth being small; there is often a double chin. The adiposity in the mammary regions is often of such extent as to suggest breast development, a feature usually embarrassing to the boy. The abdomen tends to be pendulous, and white or purple striae are often present. The external genitals of boys appear disproportionately small, but actually are of average size; the penis is often nearly submerged in the pubic fat. In a few instances the genitals do appear to be definitely smaller than would be expected for age, and puberty is delayed. The development of the external genitals is normal in the majority of girls, and menarche is usually not delayed. The obesity of the extremities is usually greater in the upper arm and thigh and is at times limited to them. The hands may be relatively small, and the fingers tapering. Genu valgum is common, and coxa vara and slipping of the epiphysis of the head of the femur (p. 1257) may occur.

Psychologic disturbances are common, but not invariably present, and even in the apparently well adjusted child adequate psychologic evaluation often discloses significant underlying emotional problems. These may have contributed initially to the obesity, and in any event are usually an additive factor.

**Treatment.** Since there appears to be no proved explanation for juvenile obesity other than excessive food intake, rational therapy consists in a reduction in the diet and an in-

Table 61. 1200-1400 Calorie Diet

Breakfast	
1 orange, ½ grapefruit or 1 cup of tomato juice	
1 egg	
1 slice of whole-wheat bread or 1 serving of cereal without sugar	
1 teaspoon of butter	
1 cup of whole milk	
Lunch	
2 ounces of lean meat, 1 egg or ½ cup of cottage cheese	
1 serving of raw vegetable as salad—no dressing	
1 slice of whole-wheat bread	
1 teaspoon of butter	
1 serving of fresh or unsweetened fruit	
1 cup of whole milk	
Dinner	
2 ounces of lean meat (liver once a week), poultry or fish	
2 servings of green, yellow or red vegetables*	
1 serving of fresh or unsweetened fruit	
1 cup of whole milk	
(Part or all of bread and butter from one of the other meals may be included here)	
A 1000-calorie diet may be obtained by eliminating the butter or cream from milk. In this case it becomes especially important to add vitamin A to the daily diet.	

\* Does not include Irish or sweet potatoes, parsnips, dried peas or beans, lima beans or corn.

crease in energy output. Emotional disturbances must be overcome and the child permitted to lead a natural active life. Children with moderate obesity in the prepuberty years require no therapy, since in the majority of them the obesity disappears during adolescence. When the dietary habits of the obese child are patterned after those of the family, as is frequently the case, treatment must include the entire family. Success in such instances is by no means universal.

In planning the diet, the basic nutritional needs (p. 133) must be met. If skimmed milk is substituted for whole milk, all the essential dietary needs may be included in a 1000- to 1200-calorie diet for children ten to fourteen years of age for several months. Some children avoid excessive eating after they have been allowed to return to a free choice of diet and may thus benefit permanently from the treatment. Protein, mostly of animal origin, should be equivalent to at least 1 gm. per pound of average weight for age, and the quantity of fat by weight should not be more than one fourth that of the carbohydrate. The diet should contain as much bulk as possible. At times greater co-

operation is secured if small portions of the diet are permitted between meals, especially in the afternoon. If there is reasonable doubt that the daily vitamin intake is adequate, vitamin concentrates may be prescribed. Vitamin D should be included, as it should for all growing children. Too rapid decreases in weight should not be attempted, and medical supervision should be maintained. The correction of any underlying emotional disturbance is essential and should include adequate adjustment of the child in physical and social activities of the home, school and community. There is at best a limited place for drug therapy. A trial with amphetamine in conjunction with dietary restriction and psychotherapy may be justified for children whose habits are quite sedentary and/or who have frequent states of depression.

## NUTRITIONAL EDEMA

(PROTEIN DEFICIENCY, HYPOPROTEINEMIA, WAR EDEMA)

During the period of growth more nitrogenous food must be consumed than is excreted (positive nitrogen balance), whereas adults need only maintain nitrogen equilibrium. Not all protein is equally efficient in the maintenance of nitrogen equilibrium or in the establishment of nitrogen retention. When the diet does not contain adequate amounts of the essential amino acids, nitrogen equilibrium is not maintained, irrespective of the total quantity of protein in the diet.

Though there are undoubtedly a number of manifestations of protein deficiency, such as inadequate growth, lack of stamina, loss of muscular tissue and increased susceptibility to infections, edema is the only one which can be considered characteristic, but even it is not specific. There is nothing to differentiate hypoproteinemic edema from that of other causes. Edema usually occurs when the serum

protein is greatly decreased, although it may occur in states of dietary deprivation without a hypoproteinemia. The function of protein in the control of water balance depends upon its osmotic effect. Though the edema level of serum protein is generally considered to be between 4 and 5 gm. per 100 ml., the serum albumin content is the most important factor, and edema tends to occur when it is below 2.5 gm. per 100 ml. Albumin has an osmotic pressure approximately three times that of globulin. The normally lower levels of serum protein in infants (4.5 to 6 gm. per 100 ml.) than in adults (6 to 8 gm. per 100 ml.) make infants especially vulnerable to protein deficiency.

The term "nutritional edema" is usually reserved for states of protein deficiency resulting from inadequate dietary intake, but hypoproteinemia sufficient to be responsible for the production of edema may also result from impaired intestinal absorption of protein (chronic diarrheal states, celiac disease), from hypogenesis of serum protein in liver disease or from renal excretion of albumin (nephrotic syndrome).

High caloric diets have a sparing action on protein, so that a smaller amount of protein may be ingested without the production of hypoproteinemia if the diet is otherwise abundant. Thus nutritional edema is more likely to occur when the diet is low in total calories and in protein.

Edema in states of nutritional deficiency is the result of a number of factors which may be operative with or without a low serum protein level. One of these appears to be an alteration in capillary permeability. Water and salt are often ingested in quantities larger than usual during periods of protein deprivation, so that they can be expected to exert a significant effect in the production of edema. Environmental temperature also seems to exert an effect in that edema tends to be more extensive in tissues relaxed by heat.

**Clinical Manifestations.** Edema, the outstanding feature, may appear abruptly and be extensive, with free fluid in the serous cavities. More frequently, however, the onset is gradual; the edema appears first in the lower extremities in ambulatory children and, unless checked, becomes generalized. In infants it is more generalized from the start, and the face especially is likely to be involved. Diets are rarely deficient in protein alone, and there are often evidences of other nutritional deficiencies, especially those of the B group of vitamins. Hypochromic anemia is

an almost constant accompaniment. The general evidences of wasting may be extreme, especially in areas of famine. The wasting, pallor, weakness, edema and potbelly present a pitiful picture.

**Prevention and Treatment.** Prophylaxis consists in an adequate protein intake. Sick children whose fluid and caloric intake must be supplied entirely or largely by parenteral means should be given amino acid solutions (2 to 4 gm. per kilogram per day); if the serum protein is low, blood or plasma may also be given.

Curative treatment in the uncomplicated case requires temporarily a high caloric, high protein diet, with much of the protein derived from milk, eggs and meat. The maintenance diet should then be an average one, but should be planned to avoid future dietary deficiency.

## KHASHIORKOR

(THIRD-DEGREE MALNUTRITION  
[GÓMEZ], PLURIDEFICIENCY SYNDROME)

*World hunger and the rise of Communism are the two things most dreaded in the free world. The two are interrelated; if we can prevent Kwashiorkor, we can prevent world hunger and other evils.—Williams.*

Kwashiorkor is the term applied to a clinical syndrome which results from a deficiency of protein and probably other nutrients, especially those of the vitamin B complex. As a clinical entity it is poorly defined, and, for practical purposes, its identification is solely by clinical means. This unique situation encompasses what is generally considered to be the most prevalent and serious nutritional disturbance and the most important medical problem among children in the world today. It is prevalent among all underprivileged peoples in the tropical and subtropical countries throughout Africa, Asia, the Far East and Central and South America. The clinical patterns vary somewhat from country to country, especially in regard to the changes of the hair and skin, but there seems to be little doubt that the basic factors are similar in all. The problem is a socio-economic one, and the real solution is educational and economic, but perhaps more could be gained quickly for world betterment by the control of this disease under medical supervision than by any other single means. The term "Kwashiorkor" is said to mean "red boy" in the "Ga" language of the Gold Coast, but another interpretation is the "syndrome of the change-

A

B

FIG. 89. A, Kwashiorkor in a 2-year-old boy. Note the generalized edema, the typical skin lesions and the state of prostration. B, Close-up of the same child showing the hair changes and psychic alterations (apathy and misery); the edema of the face and the skin lesions can be seen more clearly. (Photographs made available by the Institute of Nutrition of Central America and Panama [INCAP], Guatemala, C.A., through the courtesy of Dr. Moisés Béhar.)

ling." As will be seen in the description of the syndrome, each interpretation is meaningful in its application. The adequacy of the term is questioned by many, especially in Central and South America, but it seems well established for the present. Kwashiorkor has much in common with the *Mehlnährschaden* of Czerny and Keller in its edematous form, and with hypoproteinemic nutritional edema observed in various countries, especially in war-torn areas where starvation is common.

The syndrome (or syndromes) as it has been described among African children consists in (1) retarded growth in the late breast-feeding, weaning and postweaning ages; (2) alterations in skin and hair pig-

mentation; (3) edema usually associated with hypoproteinemia; (4) the frequent association of a variety of dermatoses; (5) fatty infiltration, cellular necrosis or fibrosis of the liver; (6) gastrointestinal disorders, including anorexia, vomiting, diarrhea and steatorrhea; (7) irritability and apathy; and (8) a high mortality rate if appropriate dietary therapy is not instituted sufficiently early. Some combination of these is essential for diagnosis.

Of 1000 cases collected by Trowell, the age distribution ranged from four months to five years, 85 per cent of the cases occurring between the seventh and thirty-sixth months. In general the affected infants appear to do

well during their early months of life while they are breast-fed; during the latter part of the first year and the early part of the second year of infancy the disease becomes prevalent. Weaning is likely to be an abrupt process among African tribes, and the new diet is high in carbohydrates and low in protein, particularly of animal origin. Cow's milk or that of other species is rarely included in the diets of these people.

Initially there is failure to grow, then loss of weight. In spite of the edema, which appears relatively early, these children are underweight and show delay in bone development. Edema usually starts in the feet, but soon involves the face, the hands, arms and genitals; ascites is rare, and effusions into the joints have not been recorded. The urine may contain small amounts of albumin, but not the large amount characteristic of nephrosis; other abnormalities of the urine are not characteristically found. There is an associated hypoalbuminemia. It is this feature in combination with the dietary history and the response to the feeding of protein of high biologic value which is responsible for the assumption that kwashiorkor is a protein deficiency state. Some emphasis has been placed on the deficiency of particular amino acids, especially methionine.

Dyspigmentation of some degree of the hair or skin is usually present and is perhaps the unique characteristic of the syndrome. The hair loses its lustre and in the Negro tends to lose its curliness and become straight and fine. It becomes pale and may be flaxen or almost reddish; in more severe forms of the disease and in other races it may become gray to white. The changes in the color of the skin are less marked and more difficult to distinguish from genetic variants. Dyspigmentation of the face is thought by some to be of nutritional origin more often than of a genetic one.

Dermatologic lesions have been observed; though skin lesions are frequently present in the well advanced cases, there is lack of agreement that any are characteristic. The possibility has been considered, but not generally accepted, that the lesions are those of pellagra. They have also been ascribed to a deficiency of vitamin A. Perhaps the commonest form is that described by Trowell:

This eruption occurs as sharply defined black varnished patches on the areas exposed to irritation (diaper area, buttocks, back and so forth) but none appears on the areas exposed to sunlight (the hands and face) on which classical pellagra should ap-

pear. These black islands rapidly enlarge, tend to coalesce and then peel to disclose a white or pink area underneath. They undergo spontaneous peeling quite independently of any specific treatment but this usually only occurs if at the same time the case is improving. (Brock and Autret.)

Widespread desquamation and scaling, amounting almost to an exfoliative dermatitis, have been described, as have thickening and fissuring of the skin (elephant skin), especially over the knees. Pemphigus-like lesions in the pelvic region in which the superficial epithelium is separated by a nonpurulent exudate have also been noted.

As the disease progresses, the child exhibits lassitude, mental apathy, photophobia and, in general, a picture of dejection and misery. The abdomen is distended, usually without ascites, and there are frequent bouts of diarrhea. The absence of pancreatic ferments has been recorded and may be responsible for the frequent occurrence of large bulky stools containing undigested material. At autopsy the disappearance of zymogen granules from acinar cells in the pancreas, atrophy of the acini and fibrosis have been observed. But in contrast to cystic fibrosis of the pancreas, the depletion of the pancreatic ferments is not permanent, if cure of the disease is effected. The principal pathologic changes are in the liver and consist in enlargement, fatty infiltration, necrosis and fibrosis.

Some degree of anemia is present in practically all instances. It is usually normocytic or slightly macrocytic, and often hypochromic. The anemia responds less slowly to high protein feeding than do other manifestations of the disease. In some instances there appears to be a favorable response to iron, but the consensus is that the anemia is not affected by vitamin B<sub>12</sub>, folic acid or liver extract.

To what extent factors other than protein deficiency are responsible for kwashiorkor or for some of the manifestations associated with it is an important question. It is probable that deficiencies of other nutrients such as of the various members of the vitamin B complex, vitamin A, certain minerals and specific amino acids are frequently contributing factors. There is also the possibility that diseases such as hookworm, malaria and dysentery may also be contributing factors in many instances. These children tolerate infections poorly, and it has been suggested that they do not tolerate antimalarial drugs in full dosage. The actual mortality rates are not known, but in the fully developed cases

FIG. 90. Jamaican infants of predominantly African stock. *Left*, Infant with "sugar-baby" kwashiorkor, showing stunting, edema of feet and hands, hepatomegaly with fatty infiltration, moon face, misery and extreme dyspigmentation of the hair (hypochromotrichia) and of the skin generally. *Right*, Normal infant of same racial group. (N.B. The hypochromotrichia here is one of the most extreme examples seen in Jamaica.) (From D. B. Jelliffe: Hypochromotrichia and Malnutrition in Jamaican Infants. *J. Trop. Pediat.*, Vol. 1.)

recovery is unusual even in hospital practice.

*Prevention* is obviously the important consideration and apparently can be accomplished by feeding an adequate diet during the postweaning phase. Because of the effectiveness of milk protein, the distribution of powdered skimmed milk protein in the indigenous areas would seem to be an effective temporary method for the rapid institution of preventive measures on a large scale. However, the problem is a much bigger one and will be solved only by the provision of adequate health facilities for all underprivileged peoples, and above all education of them in basic health measures and in improvement of their socio-economic status.

*Treatment* involves attention to the need for fluids, electrolytes, blood, plasma, a diet rich in proteins of high biologic value, vitamins and minerals and the treatment of any coexisting infections.

#### VITAMIN A DEFICIENCY

Carotenes and their derivative, vitamin A, are required in the diets of infants and children, since the human organism is unable to synthesize them. Carotenes of plant origin are readily converted into vitamin A by the liver, in which to a large extent it is stored, to be released as needed. In infants the vitamin A level of the blood plasma varies between 50 and 100 I.U.; in adults, between 100 and 300 I.U.\* In disorders of the liver, in diabetes mellitus and in hypothyroidism the conver-

\* One international unit (I. U.) of vitamin A is equivalent to 0.3 microgram of vitamin A alcohol.

sion of carotene may be disturbed, and it may appear in unusual amounts in the blood (carotenemia). In children with carotenemia the skin shows a yellow discoloration, but the color of the scleras remains unchanged.

**Etiology.** The liver of the newborn infant has a low vitamin A content which is rapidly augmented after birth, since colostrum and the initial breast milk furnish large amounts of the vitamin. Breast milk and whole cow's milk are satisfactory sources of vitamin A. When other foods (vegetables, fruits, eggs, butter, liver) or cod liver oil is added to the infant's diet, new sources of vitamin A are made available. The loss by cooking is small, since the vitamin is not water-soluble and is fairly stable to heat. Canning and freezing of foodstuffs do not appreciably affect their vitamin A content. Oxidizing agents, however, destroy this vitamin.

The danger of vitamin A deficiency is small in healthy children under normal living conditions. If, however, for economic or other reasons the diet is restricted for any length of time to flour mixtures, cereals or skimmed milk, symptoms of vitamin A deficiency are to be expected. Symptoms may also develop in spite of adequate intake of vitamin A under pathologic conditions which interfere with its absorption or storage. Chronic intestinal disorders, celiac disease and hepatic and pancreatic diseases, in which there is a disturbance of fat metabolism, belong in this category. The danger of vitamin A deficiency is augmented in these cases if fat-free diets, which are usually poor in vitamin A, are recommended for therapeutic purposes. The dietary regimens for infantile eczema are also often deficient. During infectious diseases the absorption of vitamin A and carotene may be diminished. Chronic use of liquid petrolatum also causes interference with the absorption of carotenes and of vitamin A.

**Pathology.** The functions of vitamin A include its participation in the formation of visual purple (rhodopsin) and the maintenance of the health of various epithelial cells. Characteristic changes in the covering epithelium resulting from deficiency of vitamin A include atrophy, followed by proliferation of the basal cells and the formation of stratified, cornified squamous epithelium, regardless of the original function or structure. Disturbance of function thus results from alteration of the epithelium, from loss of secretory ability and from obstruction by keratinized debris.

In the eye, in addition to night blindness, deficiency of vitamin A manifests itself by

dryness of the conjunctiva (xerophthalmia) and of the cornea, which may become soft (keratomalacia) and ulcerated. Follicular hyperkeratosis of the skin is more frequent in adults than in children. Changes in the respiratory system are especially important in infants, in whom obstruction of small bronchioles may cause patchy atelectasis and emphysema. Squamous metaplasia of the pelvis of the kidney, ureters, urinary bladder, enamel organs, pancreatic and salivary ducts may occur. In experimental animals compression of the brain and spinal cord has been observed as the result of their continued normal growth and the retarded growth of their osseous coverings.

**Clinical Manifestations.** The first symptom of vitamin A deficiency is cessation of growth. Later there is loss of weight and apathy. Night blindness, loss of visual acuity in dim light, may be due to vitamin A deficiency, since this vitamin plays an important role in the retina as a component of visual purple. After exposure to bright light the visual purple is converted to visual yellow, which partly reverts to visual purple in the dark. This latter process of regeneration of visual purple depends upon a sufficient supply of vitamin A.

Xerophthalmia and keratomalacia appear late in the disease. The first symptoms are dryness of the palpebral conjunctiva and in-

FIG. 91. Recovery from xerophthalmia, showing permanent eye lesion. (Bloch: *Am. J. Dis. Child.*, Vol. 27.)

FIG. 92. Hyperostosis of the ulna and the tibia in an infant 21 months of age, resulting from vitamin A poisoning. A, Long wavy cortical hyperostosis of ulna. B, Long wavy cortical hyperostosis of right tibia; striking absence of metaphysal and epiphysal changes. (J. Caffey: *Pediatrics*, Vol. 5. Published by Charles C Thomas, Springfield, Ill.)

jection of the bulbar conjunctiva. On the latter there are sometimes dry, yellowish patches (Bitot's spots). The dryness later extends over the cornea, which becomes cloudy and wrinkled. Photophobia is present at this stage. When the cornea becomes necrotic, superimposed infection and ulceration may be predominant. Prior to necrosis and ulceration the process is reversible when adequately treated. After ulceration has taken place healing results in formation of opaque scars and loss of vision (Fig. 91). The skin is dry and scaly, and at times follicular hyperkeratosis may be found on the shoulders, the buttocks and the extensor surfaces of the extremities.

The epithelial changes of the mucous membranes predispose to infections; pneumonia is a frequent complication and often the immediate cause of death.

**Diagnosis.** Dark adaptation tests, when made carefully and under strictly standardized conditions, may be helpful, but the method is not adaptable to routine clinical practice. If xerosis conjunctivae precedes

night blindness, it can be detected by biomicroscopic examination of the conjunctiva. Examination of the scrapings from the eye and vagina has also been recommended as a diagnostic aid. The plasma carotene level falls quickly, but the vitamin A concentration decreases more slowly. An absorption test for vitamin A is available. After fasting, a sample of blood is taken, 0.1 cc. of percomorph liver oil per pound of body weight is given, and samples are taken three, five, seven, nine and twelve hours afterwards. Low absorption curves are obtained in children with fibrosis of the pancreas, celiac disease, obliteration of the bile ducts, and cretinism.

**Prevention.** Infants should receive at least 1500 I.U. daily, older children 2000 to 4500 I.U. of vitamin A or carotene, and adults, 5000 I.U. The average diets of infants and children in this country supply enough vitamin A to prevent symptoms of deficiency. If children receive, in addition, one of the vitamin A and D concentrates or a multiple vitamin preparation, most of which contain 3000 to 5000 I.U. of vitamin A per recom-

mended dose, their requirements are more than adequately covered.

Children on a low fat diet for therapeutic reasons should receive supplementary vitamin A. In disorders which result in poor absorption of fat, water-miscible preparations of vitamin A should be administered in amounts equivalent to several times the usual daily requirement. Premature infants, who absorb fats and vitamin A less efficiently than do full term infants, should also receive water-miscible preparations.

**Treatment.** In cases of latent vitamin A deficiency a daily supplement of 5000 I.U. of vitamin A to the diet is all that is required. If symptoms are present, 20,000 to 50,000 I.U. should be given for several days, followed by the foregoing plan.

**Hypervitaminosis.** Acute hypervitaminosis A may occur in infants after the ingestion of 300,000 I.U. or more. The symptoms are nausea, vomiting, drowsiness, and bulging of the fontanel.

Chronic hypervitaminosis A appears after ingestion of excessive doses for several weeks or months. The initial manifestations are not specific. The child has anorexia, pruritus and a lack of gain in weight. There is increasing irritability, limitation of motion and tender swellings of the bones. Alopecia, seborrheic cutaneous lesions, fissuring of the corners of the mouth and hepatomegaly may develop. Roentgenograms reveal hyperostosis affecting several bones and most marked at the middle of the shafts. A history of excessive ingestion of vitamin A is helpful in the differentiation of cortical hyperostosis (Caffey's disease, p. 1260).

## VITAMIN B COMPLEX DEFICIENCY

Vitamin B complex consists of a number of separate factors which vary greatly in chemical composition and function. Three of these factors are of outstanding importance in pediatric pathology, since definite disease can be attributed to their absence in the diet. Beriberi is considered a thiamine deficiency; pellagra, a niacin deficiency; and a clinical syndrome of cheilosis, glossitis and keratitis, a riboflavin deficiency. Factors such as pyridoxine, pantothenic acid, choline, biotin, inositol, folic acid and B<sub>12</sub> are of importance for the normal functioning of the human organism, but at present no specific deficiency syndromes can be ascribed to lack of them in the diets of children. Several members of the B complex are important constituents of enzyme systems. Since many of these enzymes are closely related in their functions, the lack of one factor can interrupt an entire chain of normal chemical processes and produce diversified clinical manifestations.

Diets deficient in one factor of the B complex are frequently poor sources of other B vitamins. It is therefore not unusual to find manifestations of several B deficiencies in one patient. In such composite disease pictures a sharp separation of the symptoms caused by deficiencies of the single factors may become impossible. In the majority of instances it is advantageous to treat a patient with the entire B complex.

## THIAMINE DEFICIENCY

### (BERIBERI)

**Etiology.** Vitamin B<sub>1</sub> (thiamine) is one of the water-soluble vitamins and, as thiamine pyrophosphate or cocarboxylase, functions as a coenzyme in carbohydrate metabolism. A deficiency of this coenzyme results in accumulation of pyruvic acid in the tissues.

The foods usually given to infants—breast milk or cow's milk, vegetables, cereals, fruits, eggs—are fair sources of thiamine. Cow's milk is a better source of thiamine than is breast milk. Mothers with thiamine deficiency produce a milk deficient in thiamine, and in infants fed their milk beriberi may develop. Older children eating a mixed diet which

FIG. 93. A, Roentgenogram of an infant 18 hours old with congenital beriberi, before thiamine therapy was instituted, showing an enlarged cardiac shadow. B, Roentgenogram of the child 11 days after administration of the first dose of thiamine, showing reduction in size of the cardiac shadow. (From D. W. Van Gelder and F. V. Darby: *Congenital and Infantile Beriberi*. J. Pediat., Vol. 25.)

contains such good sources of thiamine as meats and legumes do not require supplements of this vitamin.

Thiamine is easily destroyed by heat in neutral or alkaline media and is readily extracted from foodstuffs by cooking water. The presence of a destructive enzymatic factor in certain types of fish explains why a diet low in thiamine induces beriberi rapidly when it is supplemented by such fish. The thiamine stores of the body are rapidly exhausted when the diet is free of this vitamin.

**Pathology.** In fatal cases of beriberi, lesions are located especially in the heart, peripheral nerves, subcutaneous tissue and serous cavities. The heart, particularly the right side, is dilated; the interstitial tissue is edematous; and fatty degeneration of the myocardium is commonly present. Generalized edema or edema of the lower extremities, serous effusions and venous engorgement of the viscera may be present. Microscopically the peripheral nerves reveal varying degrees of degeneration of myelin and of axon cylinders; the latter changes are more likely to be present in chronic states of deficiency.

**Clinical Manifestations.** Infantile beriberi is rarely seen in the United States. Information about it is based chiefly on reports from Oriental countries. Congenital beriberi in infants of mothers with a severe deficiency has been observed, but the majority of cases occur within the first three months of life. The vague initial symptoms are restlessness, anorexia, vomiting and constipation.

On the basis of physical findings, two types can be distinguished: In one the infants may appear plump, but are pale, flabby, listless and dyspneic; the heart rate is rapid and the liver enlarged. In the other type the infants are undernourished, pale and edematous. They too have dyspnea, vomiting and tachycardia. The knee and ankle jerks are absent in each type. There is no gain in weight except in infants who have edema, which is usually restricted to the distal parts of the extremities. The skin appears waxy. The urine may be scanty and contain albumin and casts.

The nervous symptoms are caused by changes in the central as well as in the peripheral nervous system. Apathy and drowsiness

are common. There may be ptosis of the eyelids and atrophy of the optic nerve. Hoarseness due to paralysis of the laryngeal nerves is a characteristic finding. Paralytic symptoms are rare in infants.

The cardiac signs at first are slight cyanosis and dyspnea. Tachycardia, enlargement of the liver, loss of consciousness, and convulsions may develop rapidly. The heart is enlarged, especially to the right. The heart sounds are rapid, and the second pulmonic sound is accentuated. As a rule there are no murmurs. Gallop rhythm may be present. The roentgenogram shows cardiac dilatation (Fig. 93), and the electrocardiogram indicates myocardial damage. Cardiac failure may terminate the disease in either the chronic or the acute form. In the latter it may occur with dramatic suddenness in infants previously considered healthy.

**Diagnosis.** The early symptoms, such as restlessness, anorexia, gastrointestinal disturbances, and pallor, are encountered in many types of nutritional disturbances which are not necessarily caused by thiamine deficiency. Najjar and Holt recommend a saturation test that consists in measuring the amount of thiamine excreted in the urine for four hours after the intravenous injection of 1 mg. of thiamine. The milk of thiamine-deficient mothers shows a delayed peroxylase reaction (negative Arakawa test). This test can be used when vague symptoms suggestive of beriberi are found in a breast-fed infant. A negative Arakawa test supports the diagnosis of thiamine deficiency.

**Prevention.** Thiamine deficiency in breast-fed infants is prevented by a maternal diet which contains sufficient amounts of this vitamin. The recommended daily dietary allowances of thiamine are 1.8 mg. during pregnancy and 2.3 mg. during lactation. Preparations of vitamin B complex, pork, dried brewer's yeast and whole cereal preparations enrich a mixed diet sufficiently to avoid thiamine deficiency. Attention should also be paid to the methods of preparation of the mother's diet, since cooking may reduce the thiamine content of good sources of this vitamin. The recommended daily dietary allowance of thiamine is 0.4 mg. for infants and 0.6 to 1.2 mg. for older children.

**Treatment.** If beriberi occurs in a breast-fed infant, the mother as well as the child should be treated with thiamine. The daily dose for adults is 50 mg., and for children 10 mg. or more. Oral administration is effective unless gastrointestinal disturbances prevent

absorption. In such a case, as well as in cardiac failure, intravenous or intramuscular injections are indicated. Such treatment is followed by dramatic improvement within two hours. Complete cure requires several weeks; the beriberi heart is not permanently damaged. There is often deficiency of other B vitamins in patients with beriberi; for this reason all the vitamins of the B complex should be administered in addition to large doses of thiamine chloride.

## RIBOFLAVIN DEFICIENCY

### (ARIBOFLAVINOSIS)

Riboflavin deficiency is rarely encountered without manifestations of other deficiencies of the B complex. Riboflavin is a water-soluble, yellow, fluorescent substance stable to heat and acids, but destroyed by light and alkalis. It is a constituent of many types of living cells and plays a role in cellular respiration. It occurs in large amounts in liver, kidney, brewer's yeast, milk, cheese, eggs and leafy vegetables. Cow's milk contains about five times as much riboflavin as human milk.

Riboflavin deficiency is usually due to inadequate food intake, but faulty absorption or utilization may be a contributory factor.

**Clinical Manifestations.** Riboflavin deficiency may manifest itself by cheilosis, glossitis, keratitis and certain lesions of the skin. Cheilosis begins as a pallor at the angles of the mouth, followed by thinning and maceration of the epithelium. Superficial fissures often covered by yellow crusts develop in the angles of the mouth and extend radially into the skin for distances of 1 to 2 cm. Cheilosis (*perlèche*) occurs in epidemics in institutions and in families where the diet is inadequate. In ariboflavinosis the tongue is smooth and shows loss of papillary structure.

Fissures and seborrheic accumulations may be seen in the nasolabial folds. Burning, itching, photophobia and lacrimation are the subjective manifestations of the ocular lesions. Examination with the slit lamp shows at first engorgement of the limbic plexus and later vascularization of the cornea, and interstitial keratitis. The corneal findings are not in themselves pathognomonic of ariboflavinosis. Scaly desquamation about the eyes and ears has been described. In addition, less characteristic symptoms such as general malnutrition, malaise and listlessness may be present. Ariboflavinosis is more frequent in the spring than at other seasons.

**Prevention.** The daily amount of riboflavin recommended for infants is 0.6 mg.; for children one to twelve years old, 1 to 2 mg.; and for adults, 2 to 3 mg. Riboflavin deficiency is usually prevented by a diet which contains adequate amounts of milk, eggs, leafy vegetables and lean meats.

**Treatment.** Treatment consists in the oral administration of 3 to 10 mg. of riboflavin daily. If no response is obtained within a few days, intramuscular injections of 2 mg. of riboflavin in saline solution may be made three times daily. The child should also be given a well balanced diet and, temporarily at least, more than the usual requirements of the B complex.

## NIACIN DEFICIENCY

### (PELLAGRA)

Pellagra (*pellis*, skin; *agra*, rough) probably has existed under certain unfavorable conditions at all times in all parts of the world.

**Etiology.** Pellagra is a systemic disease which affects all the tissues of the body. Though it is a deficiency disease, it is questionable whether all its symptoms can be attributed to the deficiency of a single vitamin. It is fairly certain, however, that the lack of niacin (nicotinic acid) is responsible for most of the manifestations.

Niacin and the physiologically active niacinamide have significance as components of coenzyme I, or cozymase, and coenzyme II. These coenzymes play a role in glycolysis as well as in respiration of the cells. Apparently the human organism cannot synthesize niacin and must depend on exogenous sources. Liver, lean pork, salmon, poultry and red meat are good sources of niacin, but most cereals contain only small amounts of it. Pellagra occurs chiefly in countries where corn, a poor source of niacin, is used as a basic foodstuff. Milk and eggs, which contain little niacin, are good pellagra-preventive foods, owing to their high content of tryptophane, which can be converted into niacin. Because niacin is a stable compound, there are only small losses by cooking if the cooking water is not excessive and not discarded.

The incidence of pellagra is increased in the spring and early summer months. This disorder is frequent in women in the post-partum period, since pregnancy and lactation increase the niacin requirement. Restricted diets given for therapeutic reasons can be just as deleterious as those enforced by unfavorable economic conditions, and a ca-

pricious appetite may also result in the development of pellagra. Pellagra usually does not occur in breast-fed infants.

**Pathology.** Histologically, there is edema and degeneration of the superficial collagen of the dermis. The papillary vessels are engorged, and there is perivascular lymphocytic infiltration in the dermis. The epidermis is hyperkeratotic and later becomes atrophic.

Changes comparable to those in the skin are present in the tongue, buccal mucous membranes and in the vagina. These changes may be associated with secondary infection and ulceration. Changes in the nervous system occur relatively late in the disease and consist of patchy areas of demyelination and degeneration of ganglion cells; demyelination in the spinal cord may involve the posterior and lateral columns.

**Clinical Manifestations.** The early symptoms of pellagra are vague. Anorexia, lassitude, weakness, burning sensations, numbness and dizziness may be prodromal symptoms. After a long period of deficiency the characteristic symptoms of pellagra appear. They may be classified as those of the skin, the alimentary tract and the nervous system. Severe manifestations may occur in children who have parasites or chronic disorders.

The most characteristic manifestations of the disease are the cutaneous symptoms, which may develop suddenly or insidiously and may be elicited by irritants, particularly by intensive sunlight. They first appear as a symmetrically developed erythema, usually on the backs of the hands, wrists, forearms, face, neck, feet, ankles and knees. The erythema resembles sunburn and in mild cases, especially in young children, may easily escape recognition. In more severe cases it becomes darker red, and is followed by drying, scaling and pigmentation of the epidermis (dry type). The lesions are usually sharply demarcated from the healthy skin around them, and their distribution may change frequently. The lesions on the hands sometimes have the appearance of a glove (pellagrous glove) (Fig. 94), and similar demarcations are occasionally seen on the foot and leg (pellagrous boot) or around the neck (Casál's necklace). In some instances vesicles and bullae develop (wet type), or there may be suppuration beneath the scaly, crusted epidermis; in others the swelling disappears after a short time and desquamation begins. The healed parts of the skin may remain pigmented.

The cutaneous lesions are sometimes preceded by symptoms in the alimentary tract,

FIG. 94. Pellagra in a boy 3 years of age, showing lesions on the hands and elbows and an early lesion over the nose and malar eminences.

such as stomatitis, glossitis, vomiting and diarrhea. Swelling and redness of the tip of the tongue and its lateral margins appear relatively early. Later there may be intensive redness of the entire tongue with swelling of the papillae and even ulceration.

Nervous symptoms include depression, disorientation, insomnia and delirium.

The classic symptoms of pellagra are usually not well developed in infants and children. Anorexia, irritability, anxiety and apathy are observed frequently in young children of "pellagra families." They may also have sore tongues and lips, and the skin is usually dry and scaly. There may be alternate diarrhea and constipation and a moderate secondary anemia. Children who have pellagra often have evidences of other nutritional deficiency diseases.

**Prevention.** The recommended daily allowance of niacin is 4 mg. for infants and 6 to 12 mg. for older children. A well balanced diet containing meat, vegetables, eggs and milk meets this requirement, so that supplements of niacin are necessary only in breast-fed infants whose mothers suffer from pellagra or in children on restricted diets.

**Treatment.** Children respond rapidly to antipellagral therapy. A liberal and well balanced diet should be supplemented with 50 to 300 mg. of niacin daily; 10-mg. tablets are recommended for children up to six years of age, and 20-mg. tablets for children from six years up to puberty. The tablets should be given not less than one hour apart. A smaller amount of niacin may be given intravenously, or approximately 100 mg. by hypodermoclysis

in severe cases or in those patients in whom intestinal absorption is poor. The administration of large doses of niacin is often followed within a half hour by a sensation of increased local heat and flushing and burning of the skin. These unpleasant effects are not produced by niacinamide.

Since vitamin deficiencies are rarely single, it is considered good practice to supplement the diet with other vitamins, especially with the other members of the B complex. Sunshine should be avoided during the active phase, and the skin lesions may be covered with soothing applications. A blood transfusion may be helpful in cases of severe anemia, and the less severe hypochromic ones should be treated with iron. The diet of the cured pellagrin should be continuously supervised to prevent recurrence.

### SCURVY

Scurvy is a manifestation of vitamin C deficiency. Vitamin C has been identified with l-ascorbic acid,  $C_6H_8O_6$ , a colorless, crystalline substance which can be prepared from glucose. In aqueous solution it is easily oxidized; destruction is accelerated in alkaline solutions (pH above 7) and by heating. The presence of copper, which acts as a catalyst, contributes to the destruction. In the absence of oxygen, however, and in acid solution, ascorbic acid withstands heat fairly well.

**Etiology.** Since vitamin C (ascorbic acid) is not synthesized by man, there is complete dependence upon the dietary supply. The infant is born with adequate stores of vitamin C if the mother's intake has been adequate. The vitamin C content of cord blood plasma is two to four times greater than that of maternal plasma. As a rule, breast milk contains about 4 to 7 mg. of ascorbic acid per 100 cc., thus forming an adequate source of vitamin C. However, a deficiency of vitamin C in the mother's diet may result in scurvy in her breast-fed infant. The calf is able to synthesize vitamin C, and the ascorbic acid content of cow's milk is only one fourth or so of that of breast milk. Pasteurization and passage through pipes containing a copper alloy reduce the vitamin C content of cow's milk until its antiscorbutic value becomes negligible. Therefore infants fed artificially must receive vitamin C supplements in order to avoid scurvy; such supplements will provide additional protection for the breast-fed infant.

Scurvy may occur at any age, but is ex-

tremely rare in the newborn infant. The majority of cases are seen in the latter half of the first and in the second year of life. Apparently all febrile diseases, particularly infectious and diarrheal diseases, increase the need for vitamin C; they are therefore predisposing factors in the etiology of scurvy.

**Pathology.** Deficiency of vitamin C results in defective formation and maintenance of intercellular substances in the supporting tissues of mesenchymal origin; these substances include the collagen of fibrous tissue, the matrices of bone, cartilage and dentin and the "intercellular cement" of vascular endothelium. The tendency to hemorrhage in scorbutic patients may be the result of failure of maintenance of cement substance in the walls of the vessels, or of collagen about the vessels. Although increased capillary fragility and bleeding are prominent signs, no anatomic lesions are demonstrable within the vessels. Lesions in the teeth result from defective dentin, and loosening of the teeth results from rarefaction of alveolar bone and from defective connective tissue attachments.

Endochondral bone formation ceases in the absence of vitamin C, since osteoblasts are no longer capable of forming their normal intercellular substance, osteoid. The trabeculae of calcified cartilage, normally exposed by the progressive growth of capillaries at the epiphyseal-metaphyseal junction, no longer become covered by osteoid tissue, nor are replaced by bone. These heavily calcified cartilaginous trabeculae are brittle and easily fractured (slipping or dislocation of the epiphysis). The trabeculae are surrounded by a loose, myxomatous type of tissue, poor in collagen; their cells rapidly become converted into recognizable osteoblasts after the administration of vitamin C.

Important changes also occur elsewhere in the bones. The pre-existing bone becomes rarefied, since formation of new bone does not keep pace with the physiologic destructive process. The periosteum becomes loosened, and subperiosteal hemorrhages occur, especially at the ends of the femur and tibia.

**Clinical Manifestations.** Clinical scurvy requires time for its development; after a variable period of vitamin C depletion vague symptoms of irritability, digestive disturbances and loss of appetite appear. The irritability becomes progressively greater, and there is evidence of general tenderness especially noticeable in the lower extremities when the infant is picked up or when the diaper is changed. The pain causes pseudoparalysis,

FIG. 95. Scorbutic rosary, depression of sternum and the so-called frog position.

and the legs assume the typical "frog position" (Fig. 95), which consists in semiflexion of the hips and knees with the feet rotated outward. Edematous swelling along the shafts of the legs may be found, and in some cases a subperiosteal hemorrhage can be palpated at the end of the femur. The facial expression is apprehensive. Changes of the gums, most noticeable when the teeth are erupted, are characterized by bluish-purple, spongy swellings of the mucous membrane, usually situated over the upper incisors. The swollen gums sometimes completely conceal the teeth. There may be a "rosary" at the costochondral junctions and a depression of the sternum. The angulation of the "scorbutic beads" is usually sharper than that in the rachitic rosary, since it is produced by a subluxation of the sternal plate at the costochondral junction (Fig. 95), in contrast to the widening of the softened epiphyses in rickets (p. 374).

Hemorrhages may occur in the skin, mucous membranes and in the soft tissues, as, for example, in those of the scalp. Orbital hemorrhage producing exophthalmos is rare. Blood may be vomited or passed by bowel, and there may be hematuria. Subdural hemorrhages are an occasional manifestation, whereas intracerebral hemorrhages rarely occur. A low grade fever is usually present. A moderate secondary anemia develops, but the total white blood cell count as well as the differential count is normal in uncomplicated scurvy. (See page 939 for role of vitamin C in megaloblastic anemia.)

**Roentgenographic Manifestations.** The diagnosis or exclusion of scurvy is usually based on roentgenographic changes in the long bones, especially of their distal ends. Changes, as a rule, are greatest in the area of the knee. In the early stages the appearance resembles that of simple atrophy of the bone. In the shaft the trabeculae cannot be dis-

cerned, and the bone assumes a "ground-glass" appearance. The cortex is reduced in thickness, "pencil-point thinness," and the epiphysal ends are sharply outlined. The white line of Fraenkel, which represents the zone of well calcified cartilage, can be clearly discerned as an irregular but thickened white line at the metaphysis. The epiphysal centers of ossification also have a ground-glass appearance and are surrounded by a white ring corresponding to the white line of the shaft (Fig. 97). At this stage scurvy cannot be diagnosed with certainty from the roentgenogram; if, however, under the white line at the metaphysis the zone of rarefaction becomes apparent, the roentgenogram is diagnostic. The zone of rarefaction is a linear break in

FIG. 96. "Slipped diaphysis" in scurvy. The epiphysis (E) of the humerus and calcified cartilage of the zone of primary calcification (ZPC) remained in place and in contact with the glenoid fossa. The diaphysis (D) was displaced laterally and separated from the epiphysis. The shadow (H) at the proximal end of the diaphysis represents beginning calcification of a subperiosteal hemorrhage.

FIG. 97. Roentgenograms of lower extremity. A, Early scurvy: "white line" is visible on the ends of the shafts of the tibia and fibula; rings around epiphyses of femur and tibia. B, More advanced scorbutic changes; zones of destruction (ZD) in femur and tibia. C, Healing scurvy; calcification of subperiosteal hemorrhages.

the bone proximal and parallel to the white line. It often does not traverse the shaft in its entire width and may be seen only in its lateral parts as a triangular defect (Fig. 97, B). A spur, a lateral prolongation of the white line, may or may not be present. Epiphysal separation may occur along the line of destruction with linear displacement (Fig. 96) or compression of the epiphysis against the shaft. Subperiosteal hemorrhages are not visible roentgenographically in active scurvy.

During healing, however, the elevated periosteum becomes calcified and presents a striking picture. The affected bone assumes a dumbbell or club shape, since the hemorrhage occurs at the ends of the bone and elevates the periosteum more at this site than in the middle of the shaft (Fig. 97, C). As healing progresses, the shadow of the hemorrhage becomes more intense, but diminishes in width; the rings around the epiphysal centers of ossification become more distinct, and the

zone of destruction disappears and is replaced by calcified tissue.

**Differential Diagnosis.** The tenderness of the limbs and the pain elicited by movement have often led to a false diagnosis of arthritis. The age of the patient aids in differentiating scurvy and rheumatic fever, since the latter is rare in children under two years. Suppurative arthritis or osteomyelitis does, however, occur in young children and infants and should be considered in the differential diagnosis. The pseudoparalysis of syphilis usually occurs at an earlier age than does that of scurvy, and is often accompanied by other symptoms of syphilis. The roentgenogram aids in the differential diagnosis. Poliomyelitis causes a true flaccid paralysis, and in infants the exquisite tenderness found in the limbs in scurvy is absent. Diseases of the blood, dysentery or hemorrhagic nephritis are sometimes suspected in scurvy when the hemorrhagic tendency dominates the clinical picture.

The clinical diagnosis of latent scurvy is difficult. A fasting vitamin C level of the blood plasma of over 0.6 mg. per 100 ml. aids in the exclusion of scurvy; a lower vitamin C level does not, however, prove its presence. A better index of vitamin C deficiency is furnished by determination of the ascorbic acid concentration of the white cell-platelet layer (buffy layer) of centrifuged oxalated blood. A level of zero in this layer indicates latent scurvy, even in the absence of clinical signs of deficiency. The saturation of the tissues with vitamin C can be estimated by the amount of urinary excretion of vitamin C after a test dose of ascorbic acid. During the three to five hours after the parenteral administration of the test dose, 80 per cent of the total twenty-four hour excretion can be found in the urine. Children with vitamin C deficiency excrete less ascorbic acid under these conditions than normal children with well saturated tissues.

In general, the diagnosis of scurvy is based on other than chemical data, the roentgenographic appearance of the long bones being of greatest importance.

**Prognosis.** Recovery occurs rapidly in cases correctly treated. Pain ceases in a few days, but the swelling caused by subperiosteal hemorrhage may require months to disappear. Body growth is usually quickly resumed. In unrecognized and untreated cases death is liable to occur after a few months from malnutrition, exhaustion, some complication or intercurrent disease. Permanent deformity from scorbutic lesions is uncommon; even

when there has been metaphysial separation, reconstruction is usually good without orthopedic treatment.

**Prevention.** Scurvy may be prevented by administration of a diet adequate in vitamin C. All infants, even breast-fed ones, should receive ascorbic acid (25 to 50 mg.), orange juice (1 to 2 ounces) or fresh or canned tomato juice (2 to 3 ounces) daily, beginning at two to four weeks of age. Lactating mothers should take generous amounts of vitamin C; a minimum daily intake equal to 150 mg. of ascorbic acid has been recommended. There is no reason why boiled or pasteurized milk may not be used in artificial feeding, provided vitamin C is added to the diet. The diet of older infants and children is usually varied enough to contain sufficient vitamin C, although the diets of all children should be appraised from time to time to ensure their adequacy, since scurvy can develop at any time of life. A daily intake of 25 to 50 mg. of ascorbic acid for infants, 50 mg. for children, and 75 mg. for adults is considered adequate.

**Treatment.** The administration of 3 to 4 ounces of orange juice or tomato juice daily will quickly produce healing, but ascorbic acid is preferable. The daily therapeutic dose is 100 to 200 mg. or more, orally or parenterally.

## RICKETS OF VITAMIN D DEFICIENCY\*

**Etiology.** Rickets is a systemic disease resulting from an insufficiency of vitamin D.

Secretions of the human skin contain 7-dehydrocholesterol, a provitamin D. Under natural living conditions this provitamin is

\* Metabolic Bone Disorders Simulating Rickets are described on page 1221.

activated by ultraviolet rays of the sunlight (296 to 310 microns) and converted into vitamin D, which is absorbed by the blood and distributed throughout the body.

In the temperate zones, particularly during the winter months, the sunshine is rather limited. The dust, smoke and fog, as well as the shadows cast by high buildings in cities, reduce the antirachitic potency of the sunlight and skyshine by filtering out the effective ultraviolet rays before the light reaches the skin. Sunlight which has passed through ordinary window glass is deprived of its antirachitic potency. As a rule, infants in the temperate and arctic zones escape rickets only when they receive a protective amount of vitamin D in their diet.

The natural diet of infants contains only small amounts of vitamin D; breast milk is a poor source, and cow's milk contains only 5 to 40 I.U. per quart. Sugar, cereals, vegetables and fruits contain only negligible amounts. Egg yolk contains from 140 to 390 I.U. per 100 gm.

Many sterol derivatives have antirachitic value, but only two of them, 7-dehydrocholesterol and ergosterol, are of practical importance. The biologic properties of activated 7-dehydrocholesterol resemble those exhibited by vitamin D preparations of animal origin, and it is probable that the vitamin D in fish oil is principally activated 7-dehydrocholesterol, as is the provitamin D of the skin. Ergosterol is of plant origin and is the sterol found in fungi. Irradiation transforms ergosterol into vitamin D (calciferol) with certain by-products such as tachysterol and lumisterol. Irradiated ergosterol is sometimes called vitamin D<sub>2</sub>; irradiated 7-dehydrocholesterol, vitamin D<sub>3</sub>. There is no vitamin D<sub>1</sub>.

**Contributory Factors.** Several predisposing factors determine the extent and clinical pattern of rickets.

**Rapid growth.** Rapid growth is one of these contributory factors. It is often thought that vitamin deficiencies occur chiefly in undernourished persons, but this is not true of rickets. Signs of beginning rickets may be found in infants who appear well nourished. Premature infants are especially susceptible to rickets.

**Age.** Congenital rickets occurs only under rare conditions and is caused by a deficient maternal diet. Mild rickets is frequent in the first few months of infancy when no preventive measures have been taken. Well developed rickets occurs toward the end of the first and during the second year of life. In

the later years of childhood clinical rickets becomes rare, although rachitic changes may be found microscopically.

**Race.** Negro children are singularly susceptible to rickets. Whether this is due to the pigmentation of their skin or to their living conditions has not been determined.

**Genetic factors.** Genetic factors play a minor role in infantile rickets, although an inherited growth pattern may affect the development of rickets. Multiple cases of rickets in a family are usually caused by similar unfavorable living conditions or dietary faults. In vitamin D-resistant rickets (p. 1221) genetic factors are of great importance.

**Pathology. Normal bone development.** Proceeding from the cartilaginous or epiphysal end toward the osseous portion, several fairly well defined zones are encountered in normal bone. Adjoining the zone of resting cartilage is the zone of proliferating cartilage, the cells of which are arranged in orderly columns. This zone is followed by the zone of degenerating cartilage, where the cells are swollen and the intercellular matrix is impregnated with calcium salts (zone of preparatory calcification). Proceeding toward the osseous portion of bone, the spaces resulting from the degeneration and disappearance of cartilage cells are regularly invaded by capillaries, accompanied by osteoblasts, which deposit a layer of osteoid on the exposed calcified cartilaginous trabeculae. The zone of preparatory calcification appears as a straight line in roentgen films. The osteoid deposited upon the calcified cartilaginous trabeculae is rapidly mineralized, and the calcified cartilage is resorbed and ultimately replaced by bone.

**Development of bone in rickets.** Rickets is characterized by a defective growth of bone resulting from retardation or suppression of normal growth of epiphysal cartilage and of normal calcification. These changes are dependent upon a decrease in the calcium and phosphorus salts in the serum available for mineralization. In rickets the cartilage cells fail to complete their normal cycle of proliferation and degeneration along the epiphysal-metaphysal line. This failure of degeneration of cartilage cells and the subsequent failure of capillary penetration occur in a patchy manner, the result being a frayed, irregular epiphysal line at the end of the shaft. The width of the epiphysal cartilage continues to increase, but the columns of cartilage cells are irregularly arranged, and branching vessels penetrate between these clumps of cartilage.

In addition to the failure of normal maturation and degeneration of cartilage cells, there is failure of normal mineralization of osseous and cartilaginous matrix. The zone of preparatory calcification fails to mineralize, and newly formed uncalcified osteoid is deposited. As a result a wide, irregular, frayed zone of nonrigid tissue (the rachitic metaphysis), composed of noncalcified cartilage and osteoid tissue, is produced. This zone is responsible for many of the skeletal deformities in rickets. It becomes compressed and bulges laterally, producing flaring of the ends of the bones and the rachitic rosary.

Changes occur in the bone in sites other than the epiphysial-metaphysial region. Mineralization is lacking in the subperiosteal bone, and a shell of osteoid tissue is formed which surrounds the shaft over its entire length. Pre-existing cortical bone is resorbed in a normal manner, but is replaced by osteoid tissue which fails to mineralize. If this process continues, the shaft loses its rigidity. The result is a softened, rarefied, cortical bone which is readily disturbed by stress, and deformities and fractures result.

**Healing rickets.** With healing, degeneration of cartilage cells occurs along the diaphysial border of the cartilage, capillary penetration of the resultant spaces is resumed, and calcification takes place in the zone of preparatory calcification. This calcification occurs approximately at the line at which normal calcification would have occurred had the rachitic process not supervened, and produces a line clearly demonstrable in roentgen films. As healing progresses, the osteoid tissue between this line of preparatory calcification and the diaphysis also becomes mineralized.

Osteoid tissue in the cortex and about the trabeculae in the shaft rapidly becomes mineralized. Months or years may be required to repair the deformities, and in extreme instances complete repair may be impossible.

**Chemical Pathology.** The formation of the organic matrix of the bones continues during the pathologic process of rickets, but minerals are not deposited in the degenerating cartilage and in the newly formed bone. In healthy infants the inorganic serum phosphorus level is 4.5 to 6.5 mg. per 100 ml. of serum, whereas in rachitic infants it is usually reduced to 1.5 to 3.5 mg. Though the serum calcium is usually normal, under certain conditions it too is reduced, and the child may suffer tetany.

In active rickets absorption of calcium and phosphorus from the intestine is diminished, and reabsorption of phosphates by the renal tubules is also said to be decreased. The abnormal calcium and phosphorus metabolism is corrected by vitamin D.

The phosphatase level of the serum, which in normal children amounts to 5 to 15 Bodansky units per 100 ml., is elevated in rickets to 20 to 30 units per 100 ml. in mild cases and 60 units or more in severe cases. In healing rickets it returns slowly to normal levels. The level of serum citrate and the excretion of citrate in the urine are influenced by vitamin D. The citric acid content of bone is reduced in vitamin D deficiency and increased by administration of vitamin D.

Various dietary factors play a secondary role in the etiology of rickets. The anion-cation relationships of the diet influence the absorption of calcium to some extent. Citric and tartaric acid and their sodium and potas-

FIG. 98. Line tests in rats (proximal end of tibia) (calcified tissue stained with silver appears black). A, Active rickets. FIG. 99. Rachitic rosary in a young infant. (Lyons and Wallinger: *Pediatrics and Pediatric Nursing*.)

sium salts have an antirachitic effect. A decrease in the alkalinity of the intestinal contents facilitates absorption of calcium. On the other hand, calcium deposition is hindered, and calcium may even be withdrawn from osseous tissue, by a decrease in the pH of the blood serum. In infants the absence of vitamin D is the basic factor responsible for rickets, and the disease is cured by vitamin D and not by the addition of calcium or phosphate to the diet.

**Clinical Manifestations. Early rickets.** The early recognition of rickets is important, but the early signs are difficult to evaluate. A history of inadequate intake of vitamin D is the best clue; the diagnosis can be established by roentgenographic examination.

Craniotabes, manifest as softening of the occiput or of the posterior parts of the parietal bones, may be found during the first few months of life when the rachitic process begins. Premature infants are particularly prone

to it. Palpation of the posterior half of the skull reveals soft spots of parchment-like consistency which may vary in size. There may also be softness of the borders of the large fontanel and along the sutures. Enlargement of the costochondral junctions and slight thickening of the wrists and ankles are suggestive of early rickets. The level of serum inorganic phosphorus usually falls below 3.5 mg. per 100 ml. at this time. In premature infants, however, rachitic changes may develop without hypophosphatemia.

**Advanced rickets.** Signs of advanced rickets are easily recognized, but the fully developed clinical case is rare, owing to widespread prophylactic treatment.

**HEAD.** Craniotabes may disappear before the end of the first year, although the rachitic process continues. The softness of the skull may result in flattening and, at times, permanent asymmetry of the head. The anterior fontanel is larger than normal; its closure may be delayed until after the second year of life, and the sutures remain soft and separated. The central parts of the parietal and frontal bones are often thicker than the corresponding areas of normal bones, forming frontal and parietal prominences or bosses, which give the head a boxlike appearance (*caput quadratum*). The head may be larger than normal, and may remain so throughout life. Eruption of the temporary teeth is sometimes delayed and out of the normal order. There may be defects of the enamel and extensive caries. The permanent teeth which are calcifying may be affected; usually the permanent incisors, canines and first molars show defects of the enamel, especially on the distal portion.

**THORAX.** In advanced rickets the enlargement of the costochondral junctions, the "rachitic rosary," becomes marked, and in

FIG. 100. Deformities in rickets, showing curvature of the limbs, potbelly and Harrison's groove.

many cases the beading of the ribs is not only palpable, but also visible. The costochondral junctions as well as the osseous part of the ribs gradually become softer. The sides of the thorax become flattened, and longitudinal grooves develop posterior to the rosary. The sternum with its adjacent cartilages appears to be projected forward, producing the so-called pigeon breast deformity. Along the lower border of the chest there develops a horizontal depression, Harrison's groove (Fig. 100), which corresponds to the costal insertions of the diaphragm. The chest may show a variety of other deformities, and the bones of the shoulder girdle may also be involved.

**SPINAL COLUMN.** Slight to moderate degrees of lateral curvature (scoliosis) are common, and a kyphosis may appear in the dorso-lumbar region in rachitic children who sit up (Fig. 101). Lordosis of the lumbar region may be seen in the erect position.

**PELVIS.** In children with lordosis there is frequently a concomitant deformity of the pelvis. The rachitic pelvis is not only small, but also continues to be retarded in growth. The pelvic entrance is narrowed by a forward projection of the promontory, and the exit by a forward displacement in the sagittal plane of the caudal part of the sacrum and the coccyx. In the female these changes, if they become permanent, add to the hazards of childbirth and may necessitate cesarean section.

**EXTREMITIES.** As the rachitic process continues, the epiphysal enlargements at the wrists and ankles become more noticeable. The enlarged epiphyses can be seen (Fig. 102) or palpated, but are not well visualized in roentgenograms, since they consist of cartilage and uncalcified osteoid tissue. There are various degrees and types of curving of the extremities, the legs usually being more deformed than the arms. Bending of the shafts of the femur, tibia and fibula results in bowlegs or knock knees, and the femur and tibia may also show an anterior convexity. Coxa vara is sometimes the result of rickets. If the rachitic metaphysis develops at an angle to the long axis of the shaft, bowing results which persists after healing. Bending may occur in the legs before walking is begun, although weight-bearing increases it. Greenstick fractures occur in the long bones, but seldom cause clinical symptoms.

Deformities of the spine, pelvis and of the legs result in reduction in height of the body, *rachitic dwarfism*.

**LIGAMENTS.** Relaxation of these structures, especially those of the spine and the larger joints, aids in producing deformities. This relaxation partly accounts for the production of knock knees, overextension of the knee joints, weak ankles, and scoliosis.

**MUSCLES.** The muscles are poorly developed and lacking in tone. As a result, children with well marked rickets are late in standing

FIG. 101. Rachitic spinal curvature well marked when the child is sitting.

FIG. 102. Curvature of arms, deformed "violin-shaped" chest, potbelly, enlarged epiphyses in a child 3 years of age.

FIG. 103. A, Active rickets; cupping and fraying of distal ends of radius and ulna; double contour along lateral outline of radius (periosteal osteoid). The 2 dense zones in the shaft of the ulna are calluses of greenstick fractures. B, Healing rickets after 12 days of treatment with vitamin D. Zones of preparatory calcification (ZPC); above them in the rachitic metaphyses there is beginning calcification. C, Healing rickets after 18 days of treatment. The zones of preparatory calcification are well defined, and the rachitic metaphyses appear well calcified. The epiphysis of the radius has become visible. D, Healing rickets after 29 days of treatment. Zones of preparatory calcification, rachitic metaphyses and shafts have become united.

and walking. The common condition of pot-belly (Figs. 100, 102) depends to a large extent upon weakness of the abdominal muscles, although the weakness of the gastric and intestinal walls aids in its production.

**Diagnosis. Roentgenographic changes.** The diagnosis of active and healing rickets is usually based on evidence obtained from roentgenograms of the wrists.

**ACTIVE RICKETS.** In active rickets the distal ends of the radius and ulna appear widened, concave (cupping) and frayed, in contrast to the sharply demarcated and slightly convex ends observed in the roentgenograms of normal infants. The distance between the distal ends of the ulna and radius and the metacarpal bones is increased, since the large rachitic metaphysis, which is not calcified, does not appear on the roentgenogram. The shafts show decreased density, and the trabeculae are usually prominent. In Figure 103, A, two dense areas are seen in the ulna that represent callus formations at sites of healing fractures. The outer contour of the radius appears double and could be mistaken for "periostitis." The double contour, however, represents the layer of osteoid tissue formed

by the periosteum, and not an inflammatory process.

**HEALING RICKETS.** Beginning healing is indicated by the appearance of the line of preparatory calcification (Fig. 103, B). This line is separated from the distal end of the shaft by a zone of decreased calcification, the zone of the osteoid tissue. As healing progresses and the osteoid tissue becomes calcified, the shaft "grows" toward the line of preparatory calcification (Fig. 103, C) until it becomes united with it (Fig. 103, D). At this stage the roentgenogram somewhat resembles that in cases of lead poisoning or syphilis. In healing rickets, however, the line of increased density is concave, while it is straight or convex in poisoning with the heavy metals.

**Differential Diagnosis.** The diagnosis is based on a history of inadequate vitamin D intake, on clinical observation, on roentgenographic examination and on the calcium phosphorus and phosphatase levels of the blood. A roentgenogram of the wrist provides the best means of making an early diagnosis since characteristic cupping and fraying of the distal ends of the ulna and radius occur at an early stage. In chondrodystrophy there

may be irregular concave outlines of the distal ends of the bones, but there is no fraying.

Nonrachitic craniotabes is sometimes present in the immediate postnatal period, but it tends to disappear before rachitic softening of the skull becomes manifest (second to fourth months of life). Craniotabes also occurs in hydrocephalus and osteogenesis imperfecta, but it is not difficult to differentiate these conditions from rickets.

Delayed dentition, although a symptom of rickets, is not diagnostic and is often a familial characteristic. Enlargement of the costochondral junctions occurs in rickets, scurvy and chondrodystrophy. The enlargements in rickets are rounded knobs; whereas in scurvy there is a ledgelike depression with the chondral or sternal portion lower than the osseous. It is sometimes difficult to distinguish rachitic deformities of the chest from congenital deformities. Bowlegs can be the result of rickets, but may be due to osteogenesis imperfecta, or they may be a familial characteristic. Vitamin D-resistant rickets and other metabolic disturbances with osseous lesions resembling rickets must be differentiated (see p. 1221).

**Complications.** Respiratory infections, such as bronchitis and bronchopneumonia, are common in rachitic infants. Pulmonary atelectasis is not infrequently associated with severe deformities of the chest.

Chronic gastroenteric disturbances are common; there may be either diarrhea or constipation, or the two conditions may alternate in the same patient.

Anemia due to iron deficiency or accompanying infections often develops in severe rickets. The lymph nodes are frequently enlarged, and the spleen may be palpable.

**Prognosis.** Though "spontaneous" healing of mild rickets often occurs from exposure to sunshine, severe cases require more energetic treatment. If sufficient amounts of vitamin D are administered, healing begins within a few days and progresses until the normal bony structure is restored. Recovery, however, from the bony deformities is slow; in many instances the enlargement of the epiphyses and of the rosary and the deformities of the skull disappear only after months or years of treatment. In advanced cases, especially when treatment has been insufficient, there may be permanent osseous alterations in the form of bowlegs, knock knees, curvature of the upper arms, deformities of the chest and spine, rachitic pelvis, rachitic coxa vara, and even dwarfing.

Rickets in itself is not a fatal disease, but complications and intercurrent infections such as tetany, pneumonia, tuberculosis and enteritis are more likely to cause death in rachitic than in normal children.

**Prevention. Exposure to ultraviolet light.** Rickets can be prevented by exposure to ultraviolet light or by oral administration of vitamin D. Sunlight, as a prophylactic agent, can be considered effective in the temperate zones only during the summer months.

**Administration of vitamin D.** The daily requirement of vitamin D is estimated to be 400 I.U. per day. Oral administration of vitamin D in one of the many so-called concentrates is the practical means for the prevention and treatment of rickets. Such preparations can be obtained in fish oil and in water-miscible vehicles. Some preparations contain only vitamin D, and others, various combinations of vitamins. Prophylactic measures should be used in breast-fed as well as in artificially fed infants. The daily prophylactic dose of vitamin D recommended for premature infants and for twins of low birth weight is 1000 I.U. in a water-miscible vehicle.

Much of the whole milk available in urban areas and most, if not all, evaporated milk are fortified by the addition of vitamin D concentrate, so that 1 quart of fresh, whole milk or a reconstructed can of evaporated milk contains 400 I.U. of vitamin D. It would seem reasonable not to rely upon vitamin D milk alone, but to provide added protection by the administration of an additional 400 I.U. of vitamin D in a concentrate.

Vitamin D should be administered to the pregnant or lactating mother.

**Treatment.** Natural and artificial light is effective therapeutically, but the oral administration of vitamin D is preferred. The daily administration of 1500 to 5000 I.U. (6 to 20 drops of a preparation containing 10,000 units per gram) will produce healing demonstrable on the roentgenograms within two to four weeks except in the unusual cases of vitamin D-refractory rickets.

## TETANY OF VITAMIN D DEFICIENCY (INFANTILE TETANY)

Formerly the most frequent cause of tetany was vitamin D deficiency. Tetany is associated with infantile rickets (vitamin D deficient) in less than half of the active cases, and is a rare manifestation of vitamin D-refractory rickets. The wide use of vitamin D prophylactically has eliminated tetany as a clinical problem. Occasionally it is observed in association with celiac disease, probably as a result of deficient absorption of both vitamin D and calcium. Tetany of vitamin D deficiency occurs most frequently between the ages of four months and three years; rarely is it observed before three months of age.

**Chemical Pathology.** When the serum calcium falls below 7 to 7.5 mg. per 100 ml., there is muscular irritability, resulting apparently from loss of the inhibitory control which the ionized calcium of the serum exerts upon the neuromuscular junctions. Why serum calcium is not consistently or even characteristically decreased along with serum phosphorus in rickets is not entirely clear. A possible explanation is that a compensatory hyperactivity of the parathyroid glands during the active stage of rickets maintains the serum calcium above the tetany level. Thus it is assumed that when the parathyroids do not compensate by secreting more hormone or cannot compete with extreme deficiencies in absorption, the serum calcium falls below the critical level and manifest tetany results. Tetany also occasionally occurs in infants with rickets shortly after vitamin D treatment has been started. This is assumed to be due to a rapid depletion of serum calcium secondary to increased deposition of calcium in the rachitic osteoid tissue and perhaps also to a decrease in parathyroid activity.

**Clinical Manifestations.** The symptoms are those of tetany, irrespective of the cause, and are described on page 1110. Vitamin D-deficient tetany may exist in either a latent or a clinically manifest stage. In practically

all instances there are clinical and roentgenographic manifestations of rickets.

**Latent tetany.** There are no evident symptoms, but they can be elicited by means of the Chvostek, Trousseau and Erb procedures (see p. 1112). The serum calcium level is less than 7 to 7.5 mg. per 100 ml.

**Manifest tetany.** Spontaneous clinical manifestations consist of carpopedal spasm, laryngospasm and convulsions. The serum calcium is often well under 7 mg. per 100 ml.

**Diagnosis.** The diagnosis is based on the combination of rickets, low serum calcium and the symptoms of tetany. The serum phosphorus may be low, normal or elevated; the serum phosphatase is increased. In the differential diagnosis other causes of tetany must be eliminated.

**Prognosis.** The prognosis is good unless treatment is delayed. Death is rarely due to tetany, although it may result from laryngospasm and possibly from cardiac dilatation, so-called cardiac tetany. Proper prophylactic treatment prevents subsequent attacks. The course need not be prolonged beyond that of the immediate attack.

**Prevention.** Prophylactic treatment is identical with that for rickets (p. 377).

**Treatment.** Active treatment is designed to raise the serum calcium above the tetany level. This may be attained by administration of calcium chloride in 10 per cent solution. For the first day or two, 4 to 6 gm. daily may be given in 1-gm. doses, the initial dose being 2 or 3 gm.; smaller doses of 1 to 3 gm. a day should then be continued for another week or two. When oral medication is impractical, calcium gluconate (5 to 10 cc. of a 10 per cent solution) can be administered intravenously, but not subcutaneously or intramuscularly, because of the dangers of necrosis.

Oxygen inhalation is indicated during convulsive seizures. When intravenous administration of calcium gluconate does not quickly control the attacks, sodium phenobarbital may be given intramuscularly (p. 1122). Parathyroid hormone in a dose of 10 to 30 units may be given in acute cases, but is rarely necessary and should not be repeated because of its rachitic effect. Dihydrotachysterol is contraindicated because of the slowness of its action and because it also is rachitic. Intubation is only occasionally necessary in prolonged attacks of laryngospasm, which is usually controlled by sedation and the administration of calcium salts. After the acute manifestations have been controlled vitamin

D administration in daily doses of 4000 to 5000 I.U. should be started and the oral administration of calcium continued (see above). When the rickets is healed, the dose of vitamin D should be decreased to the usual prophylactic one.

WALDO E. NELSON

## VITAMIN K DEFICIENCY

The exact function of vitamin K is uncertain; it is essential for the formation of prothrombin; absence of the vitamin or failure to absorb it from the intestinal tract results in hypoprothrombinemia.

Prothrombin may be measured by the two-stage method of Warner, Brinkhouse and Smith or by the simpler one-stage method of Quick. The latter technique measures in terms of "prothrombin time" the rate of clotting of oxalated blood after the addition of an excess of thromboplastin and calcium. Prothrombin with thromboplastin and calcium forms thrombin, which then joins with fibrinogen to form fibrin. With an adequate intake and absorption of vitamin K, prothrombin deficiency may occur in the presence of liver damage.

**Sources of Vitamin K.** Naturally occurring vitamin K is fat soluble and found in high concentrations in hog's liver, soy beans and alfalfa, and in smaller amounts in some vegetables such as spinach, tomatoes and kale. The natural vitamin, whose formula is 2-methyl-3-phytyl-1, 4-naphthoquinone, has been labelled vitamin K<sub>1</sub> to distinguish it from synthetic naphthoquinones with vitamin K activity, of which menadione (2-methyl-1, 4-naphthoquinone), a fat-soluble preparation, and Hykinone and Synkavite, water-soluble preparations, are examples.

Many bacteria, including normal intestinal flora, are capable of synthesizing quinones with vitamin K activity. Suppression of intestinal bacteria by various antibiotics may result in vitamin K deficiency with a diminution of prothrombin.

**Clinical Manifestations.** Deficiency of vitamin K, or hypoprothrombinemia, should be considered in all patients with a hemorrhagic disturbance. Such hemorrhages may be cutaneous or internal, or both. Since naturally occurring vitamin K is fat soluble, most instances of vitamin K deficiency in childhood are due to states affecting absorption or utilization of fat such as prematurity, chronic diarrhea, the celiac syndrome, sprue, and

obstructive lesions of the biliary tract. Diseases of the liver such as severe hepatitis, acute yellow atrophy, or cirrhosis giving rise to hypoprothrombinemia cannot strictly be listed as manifesting vitamin K deficiency, since intake of this vitamin may be normal, but damage to the liver prevents utilization of the vitamin in the production of prothrombin. Hemorrhagic disease of the newborn (p. 336) is considered to be due to vitamin K deficiency, but the exact role of liver insufficiency in this condition is undetermined.

Hypoprothrombinemia may also result from administration of certain drugs. Dicumarol, obtained from spoiled sweet clover, is used specifically for the production of hypoprothrombinemia in the prevention and treatment of venous thrombosis. It is thought that Dicumarol prevents the liver from utilizing vitamin K and has no direct effect on prothrombin. Blood prothrombin is continually destroyed in the body; since Dicumarol prevents its replacement, a fall in prothrombin occurs. If a dangerously low level results, massive doses of vitamin K<sub>1</sub> may be necessary to restore the prothrombin to the normal level. If the administration has been delayed too long, whole blood transfusions may be necessary.

Salicylic acid, a degradation product of Dicumarol, produces hypoprothrombinemia by similar action. The fall in prothrombin resulting from the use of salicylates, however, is only mild as compared with that brought about by Dicumarol. The hemorrhagic manifestations in acute rheumatic fever in some instances may be due to large doses of salicylates. Vitamin K is effective in neutralizing the action of salicylates, and its routine use in children receiving large doses of salicylates is recommended.

**Treatment.** Mild prothrombin deficiency may be corrected by oral administration of vitamin K, using the water-soluble preparations for patients who absorb fat poorly. One to 2 mg. daily for an infant will usually suffice. If prothrombin deficiency is severe and hemorrhagic manifestations have appeared, vitamin K should be given parenterally; the preparation of choice is the naturally occurring fat-soluble vitamin K<sub>1</sub> or its oxide. Both are equally effective and are superior to water-soluble synthetic preparations. In such instances 5 mg. should be administered daily. Larger doses should be avoided, especially in premature infants; synthetic vitamin K can produce hemolysis of red blood cells

containing low levels of glutathione and may be responsible for hyperbilirubinemia and kernicterus in premature infants. To date there has been no demonstration of hemolysis with administration of vitamin K<sub>1</sub>. When hypoprothrombinemia is due to liver damage, whole blood should be given; it need not be fresh, since prothrombin in stored blood is quite stable.

## INFECTION, IMMUNITY AND ALLERGY IN RELATION TO PEDIATRICS

### *THE PHYSICIAN'S RESPONSIBILITY IN THE FIELD OF INFECTIOUS DISEASE*

The prevention and treatment of infections account for a large part of pediatric practice. The clinical pattern of different infections evolves with age, from the infantile response to the fully developed reaction of the adolescent or adult. Growth and development, which differentiate pediatrics from adult medicine, affect all the phenomena of infection, immunity and allergy in childhood; knowledge of these is vital to the pediatrician. He should also be familiar with the principles of epidemiology, since he must learn to look at a case of infectious disease in relation to its setting. Often the symptoms in his patient are only part of an epidemic pattern involving other members of the household or a larger group in the community. He should also appreciate the variability in clinical manifestations of many infections, such as those due to the poliomyelitis viruses or the meningococcus, in which mild or inapparent infection is the rule and the classic case of poliomyelitis or meningococcal meningitis is the occasional exception. The epidemiologic approach to a patient with infectious disease will not only assist in diagnosis, but also, if coupled with prompt reporting to the public health authorities, may play an important role in protection of the community.

### *GENERAL PRINCIPLES OF IMMUNOLOGY*

The responses of the organism to the stimulus of infection or of contact with certain foreign chemical substances are *specific* against the particular pathogenic agent and lead to a state of heightened resistance (*immunity*) and frequently to a state of hypersensitivity (*allergy*) as well.

Landsteiner's work demonstrated that the specificity of an immune response is determined by the chemical structure of the substance eliciting it, i.e., the antigen. Most

infectious agents call forth immune responses to the antigens they contain or secrete during the processes of growth. The capacity of antigens to induce the formation of antibodies or the development of hypersensitivity can be greatly enhanced by injecting them with adjuvants, such as mineral oil, killed tubercle bacilli or colloidal aluminum hydroxide, the substance used in the preparation of alum toxoids.

The clinical and pathologic manifestations of an infectious disease are the result of the interplay between the multiplying organism and the nonspecific and specific defenses of the host. During its growth the organism may release irritating substances from itself or from the tissues, giving rise to local and distant tissue changes, or it may act as little more than an inert foreign body until the allergic state develops and a more violent reaction takes place (tuberculosis, trichinosis). Certain types of infections call forth characteristic responses, such as the leukocytosis, polymorphonuclear exudate and elevated sedimentation rate of an acute pyogenic infection, or the normal leukocyte count, lymphocytic exudate and normal sedimentation rate of many viral infections. These can be important clinical guides to correct diagnosis and treatment.

The lymphoid tissues appear to be the principal source of the specifically modified serum gamma globulins, termed antibodies, which appear in the general circulation within a few days after antigenic stimulation. The antibody-producing cells retain an enhanced power of reaction to the same stimulus for a long time, so that a subsequent injection of antigen will call forth a more rapid appearance of antibodies, which will usually rise to a higher titer and persist longer than after the first injection. This is the basis for the use of "booster" doses of toxoids or vaccines.

The development of specific immunity is

closely related to the development of specific hypersensitivity or allergy, i.e., the property of reacting violently to ordinarily innocuous doses of an antigen. Two types of allergy may be broadly distinguished. The first or *anaphylactic* type, associated with the presence of antibody in the circulation, manifests itself by a histamine-like immediate skin reaction when the antigen is injected intradermally and by immediate and violent symptoms when it is injected intravenously. It is characteristic of the sensitivity to foreign proteins and the common allergens for constitutionally allergic persons (ragweed pollen, egg white, wheat, milk proteins, and so forth).

The second or *bacterial allergic* type of hypersensitivity (tuberculin) frequently develops as a response to an infection and is characterized by a lack of antibody in the serum, but may be passively transferred by lymphoid cells from a hypersensitive person. Intradermal injection of the antigen in a sensitized person results in a delayed (forty-eight hour) reaction with redness and induration; parenteral administration may result in fever and malaise and in focal reactions in areas of disease after a period of several hours. This type of sensitivity occurs in tuberculosis, brucellosis, tularemia and many other bacterial infections, in histoplasmosis, coccidioidomycosis and other fungus diseases, and in many viral diseases, notably lymphogranuloma venereum and mumps.

Although specific immune responses have been studied intensively, many nonspecific factors which play an important role in resistance to infection are poorly understood because they are difficult to study under controlled conditions. Animals can be bred for resistance or susceptibility to certain types of infection or anaphylactic sensitization. The low resistance of the premature infant is obvious, but not adequately explained. Nutritional and physiologic factors are hardest to evaluate. Clinically, undernutrition is associated with increased morbidity and mortality from many infectious diseases, but undernutrition usually occurs under crowded and unsanitary living conditions, which may be more important in the spread of infections.

The normal response of the adrenal cortex under the influence of the anterior lobe of the pituitary gland is important in protecting the individual against the metabolic stress of acute infections. However, large doses of cortisone may activate latent infection in experimental animals, and therapeutic doses in man may not only suppress the symptoms

of infection, but also render ordinarily mild infections such as varicella very severe.

## PEDIATRIC IMMUNOLOGY

Growth and development have an important influence on the reaction of the child to infection and on the evolution of the immune state.

### INFECTION

The incidence of different infections varies markedly at different ages. In large measure this is due to changes in immunity and to varying opportunities for exposure, but there is little doubt that tissues at various ages provide different conditions for the growth of microorganisms. During prenatal existence infection of the fetus is possible only if microorganisms invade the maternal blood stream and cross the placental barrier. In the early stages of pregnancy death of the fetus or congenital anomalies may arise either as indirect effects of maternal infection on the nutrition of the fetus or as the result of direct infection of fetal tissues. The agents of syphilis and toxoplasmosis can pass the placental barrier in the latter part of pregnancy; mumps, chickenpox and measles of the newborn resulting from intrauterine infection have also been described. Other infections are transmitted only during passage through the birth canal. During neonatal life certain bacterial infections, notably those due to *Staphylococcus aureus* and *Escherichia coli*, are far more prevalent than later.

Age influences the course and severity of infections. Bacterial diseases which may occur at any age, such as tuberculosis, vary characteristically in different age groups. In infancy they are likely to be severe and rapidly progressive, with a relatively high mortality and a decided tendency to hematogenous dissemination and the development of meningitis. Mortality and severity fall to their lowest points between the ages of three and ten years. With the approach of adolescence, severity and mortality begin to increase and rise steadily to reach their peak in later life. Many viral infections, notably chickenpox, measles, epidemic hepatitis and poliomyelitis, tend to be much more severe in the adult than in the child.

Part of the changing picture of infection at different ages is doubtless related to the development of hypersensitivity and immunity. The infant may suffer a generalized infection on initial contact with *Hemophilus*

*influenzae B* or herpes simplex virus; the immune adult has only local infection with these agents. Boisvert and his colleagues emphasized the contrasts between hemolytic streptococcal infections in infancy, childhood and adult life. They used the term "streptococcosis" to bring out the similarity between the over-all pattern of this infection and tuberculosis. In infants primary hemolytic streptococcal infection is characterized by a prolonged, irregular course, in which constitutional symptoms may be mild except for the occasional appearance of high fever, but in which fulminating bacteremia akin to miliary tuberculosis may develop. Later in childhood, scarlet fever becomes a more common form of disease caused by this organism; in adolescence and adult life it most often manifests itself as acute tonsillitis, with abrupt onset, severe constitutional symptoms and a relatively short course.

### IMMUNITY

The exchange of antigens and antibodies between mother and fetus in utero was clearly established by Levine in his work on erythroblastosis fetalis. He showed that this disease develops as a result of iso-immunization of the mother by antigenic material from the fetus, with subsequent passive transfer of the resultant antibodies from maternal to fetal circulation, where they react with fetal erythrocytes. Reversal of this process (iso-immunization of the fetus by maternal antigens) has never been demonstrated; perhaps this is a human counterpart of the phenomenon of acquired tolerance for tissue cells of another strain after injection of such cells during fetal life, as shown in mice by Billingham et al.

The fetus does not appear to synthesize antibodies or gamma globulins in contrast to most other serum proteins, but receives these from its mother by way of the placenta. The role of colostrum in the transfer of antibodies from mother to newborn infant, although essential in the cow, with its placental structure, has not been shown to be important in the human being.

The infant born at term has a level of serum gamma globulins and immune antibodies corresponding to those of the mother, from whom they were derived in utero. The quantities of certain of these antibodies, if present—for example, protective antibodies against measles and epidemic hepatitis—are sufficient to prevent or modify these infections in the infant for the first six to eight

months of life; levels of various antibacterial antibodies are only adequate to protect the child for a month or so. Synthesis of the child's own gamma globulins or antibodies does not ordinarily begin until the third or fourth week of life; consequently the serum levels of gamma globulin and antibodies normally decrease during the first month to values somewhat below one-half those at birth. Subsequently, as the capacity for gamma globulin synthesis increases, its serum level gradually rises to reach the normal adult range (800 to 1200 mg. per 100 ml.) at one to three years of age. The pattern of immune antibodies within the gamma globulins develops throughout life in response to a continuing succession of antigenic stimuli from infections and active immunizations.

Although the capacity of the young infant to form antibodies is less well developed than that of the older infant, this does not justify deferment of basic immunization, since a subsequent booster injection appears to be about as effective whether basic immunization was started at one month or six months of age.

### ALLERGY

Whether the ability to respond to antigens with the development of specific hypersensitivity varies greatly at different ages is not clear. In general, the incidence of hypersensitive reactions to therapeutic antisera or drugs is somewhat less in young children than in older children, adolescents and adults. Delayed hypersensitivity develops with great regularity in children of all ages in infections such as tuberculosis, although it may not be so intense in infants as in older persons. Late nonsuppurative complications of hemolytic streptococcal infections, rheumatic fever, acute glomerulonephritis, erythema nodosum, thought by many to be reactions of hypersensitivity to bacterial antigens, occur most frequently in childhood.

The responses of persons with inherited allergic (or atopic) tendencies follow a regular pattern as growth and development proceed. Passive transfer of allergens from mother to fetus by way of the placenta and to infant by way of the colostrum and milk has been suggested as a mechanism for early initiation of hypersensitivity. Although skin-sensitizing antibodies (atopic reagins) characteristic of hypersensitive individuals do not cross the placental barrier, so-called blocking antibodies induced by "hyposensitizing" injections of allergens do so. In infancy the skin is often the first organ to react, and atopic eczema serves

as an indicator of a highly atopic constitution. Many allergic responses, such as those of hay fever, asthma, gastrointestinal symptoms, chronic eczema, urticaria or angioneurotic edema, are likely to come and go or become chronic as the patient grows to adulthood. The allergic picture may be modified by endocrine, psychologic and infectious factors, but the allergic response represents an inherited tendency for exaggerated local responses to many antigens.

It is to be hoped that advances in such fundamental sciences as protein chemistry and enzymology will ultimately explain the underlying mechanisms of infection, resistance and allergy sufficiently to provide a rational interpretation of some of the confusing and complex biologic phenomena with which the pediatrician must deal.

CHARLES A. JANEWAY

## CLINICAL USE OF THE MICROBIOLOGY LABORATORY

Much of the responsibility for attaining satisfactory laboratory diagnosis and hence control of infectious diseases rests with the clinician. It is he, not the laboratory worker, who decides what specimens to collect, how to obtain them and which laboratory procedures to request. He must also see that specimens are preserved properly until they can be delivered to the laboratory. Finally, he should be competent to make the correct interpretation of the results. In institutional practice skilled laboratory personnel are usually available for consultation; otherwise the physician must rely upon his own knowledge and judgment.

**Choice of Specimens.** The choice of specimens to be examined often makes the difference between success and failure. The clinician, in many instances, will be guided by the patient's signs and symptoms as to the type of etiologic agent he should suspect. In other instances the signs and symptoms may be so nonspecific that he must ask the laboratory's help in ruling out a variety of agents. Material from the system of the body chiefly involved should be collected, e.g., cerebrospinal fluid from a patient with meningeal symptoms or blood from a patient with fever of undetermined origin. Consideration

should also be given to possible portals of entry, such as the upper respiratory tract in patients with meningeal involvement.

In the choice of specimens one must decide whether an attempt should be made to isolate the etiologic agent, demonstrate the antibody response, or both. In bacterial infections the method of choice is the demonstration of the offending organism by smear and culture, provided the disease is of short duration. As the infection progresses, however, isolation technique may fail, and serologic tests should also be requested. In viral infections isolation is seldom practical, and the diagnosis usually rests upon demonstration of a rise in the specific antibody titer.

**Collection and Preservation of Specimens for Isolation of Etiologic Agent.** Care must be taken to avoid contamination from the skin, air or unsterile objects during the collection of body fluids; costly delay occurs when the laboratory identifies an unimportant contaminating bacterium or fungus. Superficial contaminants may be removed from skin lesions by swabbing the area with an alcohol sponge. It is rarely feasible to try to remove the normal flora from infected mucous membrane. Usually an almost pure culture of the offending organism can be ob-

tained by applying a dry cotton swab directly to the affected region.

The cotton swab is satisfactory for the collection of specimens from skin and mucous membranes. The preservation of swab specimens is too often neglected, however. They should be kept moist by placing them in a small amount of culture broth (see Fig. 104), since drying is rapidly destructive to many pathogenic bacteria and viruses. Specimens of body fluids and tissues obtained by biopsy or at autopsy should be secured aseptically and placed in sterile glass containers. All specimens should be delivered to the laboratory as promptly as possible. See Table 62 for special techniques applicable to the various types of infecting organisms.

**Bacteria, fungi and protozoa.** Fungal specimens do not require prompt attention, but immediate study of bacteriologic and parasitologic specimens is always desirable and in some instances essential. For example, darkfield examination for spirochetes is practically useless thirty minutes after the material has been collected. Whenever there is delay in transferring bacteriologic specimens to the laboratory, they should be stored in the refrigerator, but should not be permitted to freeze.

Purulent fluids, including cerebrospinal fluid, may coagulate on standing, so that accurate cell counts become impossible and detection of microorganisms is difficult. It is advisable, therefore, to add a few drops of anticoagulant at the time of collection.

**Viruses and rickettsiae.** These organisms may also be collected by means of swabs. However, in order to obtain viruses from the respiratory tract, throat washings with a buffered saline solution or a mixture of half saline and half broth can be collected. Cerebrospinal fluids from patients with viral infections of the central nervous system do not have a high protein content, so that, in contrast to the treatment of purulent specimens, anticoagulants should not be added, since they may affect the viability of any virus present. All viral specimens should be frozen as soon as possible and conveyed to the laboratory in the frozen state by means of dry ice, since preservation of viruses is facilitated by freezing.

**Collection and Preservation of Specimens for Serologic Tests.** Correct use of serologic tests for diagnosis requires at least two blood specimens. The first should be taken at the time of the first examination ("acute serum"), the second five to fourteen

days later or during convalescence ("convalescent serum"). Great care must be taken to avoid contamination and hemolysis. An aseptic venous puncture, removal of the needle before emptying the syringe into the tube, avoidance of air bubbles and early separation of serum are essential. Serum should be frozen for preservation, *but whole blood should never be*.

**General Consideration of Methods.** There are two principal types of diagnostic procedures in microbiology. The first is the direct method, whereby the infectious agent is identified in clinical material by direct microscopy, culture, injection into susceptible laboratory animals or by a combination of these methods. The second is the indirect approach through the detection of specific antibody either by skin tests or by serologic procedures. In general the direct method yields more reliable information for the diagnosis of bacterial, parasitic and mycotic infections in their early phase, whereas the immunologic response is more likely to provide diagnostic information when the infection is caused by viruses, rickettsiae and spirochetes, and when certain bacterial in-

FIG. 104. Throat and nasopharyngeal swab outfit. A, Wooden swab for collection of material from the throat and tonsils or for general use. B, Wire swab for collection of nasopharyngeal specimens. Both are contained in sterile cotton-plugged test tubes. After the test material has been obtained the swabs are immersed in the broth in the inner tube.

fections are investigated late in their course. When the diagnosis depends on serologic methods, it may not be available until after recovery from the illness.

**Direct visualization.** In bacterial infections this method is limited to specimens derived from areas of the body which normally are sterile and to the recognition of bacteria that can be identified by their shape or by some unique staining property. For fungi and parasites direct microscopy, however, is a valuable step in the laboratory diagnosis. In viral infections this type of study may reveal characteristically altered host cells which are of immediate aid in making a differential diagnosis.

**Isolation procedures.** Laboratory culture is the mainstay of bacteriologic and mycologic diagnosis; precise identification of most pathogens is almost impossible in any other way. On the other hand, the parasitologist seldom uses this method.

Since viruses and rickettsiae cannot be cultured in the absence of living tissue, the virologist must make use of living hosts for isolation purposes; these include the chick embryo, various species of laboratory animals, and living cells of human or animal origin growing in tissue culture.

**Serologic methods.** The host produces antibodies in response to infection even when it is subclinical. The amount of antibody produced increases with severity, but varies with the kind of infection. Enteric gram-negative bacilli and exotoxins elicit the greatest immunologic responses. Fungi and animal parasites as a rule are poor antigens, whereas viruses generally produce good titers of antibody.

Antibody can be detected and specifically identified by serologic methods in vitro and in vivo by skin and neutralization tests. For most bacterial and leptospiral infections the method of choice is the agglutination test, using either the intact cell or a fraction of it adsorbed upon a particulate carrier such as type O human erythrocytes. The complement fixation test is used primarily for syphilis. The only important skin test for the diagnosis of bacterial infections is the tuberculin test, but other allergic skin tests could be developed if they were needed. Although the use of the complement fixation test is gradually increasing in the diagnosis of fungus and parasitic infections, the necessary antigens are not available to the average hospital laboratory. On the other hand, allergic skin tests are important in the diagnosis of

fungus and a few of the parasitic diseases, notably trichinosis.

Owing to the difficulties associated with the isolation of rickettsiae and viruses, much effort has gone into the development of satisfactory methods for the serologic diagnosis of these infections. The method most commonly used is the complement fixation test, for which a number of commercially prepared antigens are available. Certain viruses, such as those of influenza and mumps, have the capacity to agglutinate erythrocytes, a property that provides a means for measuring the corresponding antibodies by the extent to which a serum sample specifically inhibits hemagglutination. In a few viral, or presumably viral, infections for which no specific antigen is available certain nonspecific antigens are agglutinated by the serum of infected persons. For example, a rickettsial infection must be suspected when the patient's serum agglutinates one of the OX strains of *Proteus*. The presence of agglutinins for the MG strain of *Streptococcus* or cold agglutinins for type O human erythrocytes is formed in association with some types of so-called primary atypical pneumonia; in infectious mononucleosis there is usually a significant rise in the titer of a certain type of heterophile antibody.

The presence of viral antibody can also be demonstrated by the neutralization test: serum inactivation of live virus when mixed with the patient's serum. The neutralization test can be applied to all viral infections for which there is a suitable experimental host, e.g., chick embryo, mouse, tissue culture. Although it has a high degree of accuracy, the neutralization technique, when adequately controlled, is both tedious and expensive; therefore its use is limited to those viral infections which cannot be diagnosed by the complement fixation or hemagglutination inhibition tests.

**Interpretation of Results.** Interpretation of certain bacteriologic data is complicated by the presence of normal flora. Throat cultures constitute a particularly difficult problem because they usually contain many kinds of colonies. Occasionally the pathogen may be selected by means of its colonial and microscopic appearance, but often an identification made on such a basis is misleading. No informed person would conclude that all intestinal gram-negative bacilli are pathogenic simply because that class of bacteria includes some disease-producing types. Similarly, it

(Text continued on page 394.)

Table 62. Selection of Diagnostic Microbiologic Specimens

<i>Suspected Infection</i>	<i>Specimen</i>	<i>Handling of Specimen</i>	<i>Laboratory Tests</i>
<b>Respiratory tract</b>			
Bacterial and fungus			
Streptococcus	Nasopharyngeal swab or throat swab	Place in 0.3 ml. of culture broth <sup>1</sup> . In case of delay, refrigerate until cultured	Culture <sup>2</sup> and antibiotic susceptibility tests Serologic typing of streptococci, pneumococci, <i>H. influenzae</i> and <i>Salmonellae</i> *
Staphylococcus			
Pneumococcus			
Meningococcus			
<i>H. influenzae</i>			
Coliform bacilli			
Proteus species			
<i>Pseudomonas aeruginosa</i>	Sputum	Collect in sterile glass containers. If stored, refrigerate	Same
Salmonella species	Bronchial aspirate*	Same	Same plus acid-fast smear
<i>Candida albicans</i>	Blood, whole, 10 ml.*	Add directly to culture broth at 37° C.	
Diphtheria	Laryngeal, pharyngeal, tonsillar or nasopharyngeal swabs	Smear on glass slides  Place one swab on Loeffler's slant; inoculate another to tellurite agar. Keep at 37° C.	Microscopic examination of special-stained smears  Culture (special method), animal toxigenicity tests and antibiotic susceptibilities
Pertussis and parapertussis	Nasopharyngeal swab	Inoculate directly to special agar plate or Place in 0.3 ml. of culture broth. <sup>1</sup> If stored, refrigerate	Culture on Bordet-Gengou agar containing 0.2 unit of penicillin
Tuberculosis	Sputum, first morning or a 24-hour specimen	Collect in sterile glass container. If stored, refrigerate	Direct smear (special stain) Culture (special method)
	Bronchoscopic aspirate*	Same	Same
	Gastric lavage (50-100 ml. of saline before breakfast)*	Same. If stored, adjust to pH 6.5-7.0 and refrigerate	Same, and inoculate guinea pigs with culture growth
Viral and rickettsial <sup>3</sup>			
Atypical pneumonia	Lung (autopsy)*	Collect in small portions in sterile tubes and freeze in dry ice	Virus or rickettsial isolation <sup>7</sup>
Psittacosis	Sputum, throat washings or throat swab*	Collect in sterile nutrient broth. Freeze in dry ice	Same
Q fever		Collect in sterile tube. Separate serum. Freeze and store for later test	Comparative complement fixation tests using appropriate respiratory viral antigens
Adenovirus	Blood, clotted, 5-10 ml. (acute phase)		
Myxovirus <sup>4</sup>			
CCA <sup>5</sup>			
ECHO			
"Cold viruses" <sup>6</sup>	Blood, clotted, 5-10 ml. in 14-18 days (convalescent)	Collect in sterile tube. Separate serum	Cold agglutinin and Streptococcus MG agglutinin tests with both serums

See page 394 for footnotes.

Table 62. Selection of Diagnostic Microbiologic Specimens (continued)

<i>Suspected Infection</i>	<i>Specimen</i>	<i>Handling of Specimen</i>	<i>Laboratory Tests</i>
<b>Gastrointestinal tract</b>			
Bacterial and fungus			
Shigellosis	Rectal swab (repeat if negative)	Culture at once or place in 0.3 ml. of buffer solution. <sup>8</sup> If stored, refrigerate	Culture <sup>2</sup> Sulfonamide and antibiotic susceptibilities Serologic typing of shigellae and enteropathogenic <i>E. coli</i>
With <i>Proteus</i> , <i>Pseudomonas</i> , <i>Aerobacter</i> , <i>Staphylococcus</i> or <i>Streptococcus</i>			
With enteropathogenic <i>E. coli</i>			
Moniliasis			
Salmonellosis	Blood, whole, 10 ml.	Add directly to culture medium. Place at 37° C.	Culture (special methods) and antibiotic susceptibilities
Typhoid fever	Blood, clotted, 5 ml. (repeat in 5-7 days)	Collect in sterile tube. Refrigerate	Agglutinin titer for groups B, C and D (preliminary, followed by repeat test with paired serums) Vi agglutination for typhoid <sup>7</sup> Culture and antibiotic susceptibilities
	Urine; voided if male, catheterized if female*	Collect in sterile tube or flask. If stored, refrigerate	
	Sputum*	Same	Same
	Swab of localized exudate*	Same	Same
<b>Parasitic</b>			
Amebiasis	Fresh stool after purgation and another after a saline enema	Collect in glass or waxed cardboard container. Examine at once. Keep at body temperature	Microscopic examination for trophozoites of <i>E. histolytica</i>
	Sigmoidoscopic aspiration (repeat at 5-7 days if negative)	Collect in test tube and place in glass of warm (37°-40° C.) water	Same
	Stool	Collect in waxed cardboard container	Microscopic examination for <i>E. histolytica</i> cysts
<b>Oxyuriasis</b>			
	N.I.H. cellophane swab (see p. 580) or	Collect by rolling swab over perianal and perineal skin in early morning	Microscopic examination for characteristic ova
	Scotch tape, 2-inch strip on wooden tongue blade	Same	Same
<b>Tapeworms</b>			
Hookworm	Stool	Collect in any suitable container. Examine at once or refrigerate	Examination for worm segments or ova in direct smears and concentration smears
<b>Viral<sup>3</sup></b>			
Enteroviruses	Stool	Collect in suitable container. Freeze in dry ice	Inoculation of suckling mice, tissue culture
Poliomyelitis			
ECHO			
Coxsackie	Blood, clotted, 5-10 ml. (acute phase)	Separate serum, freeze and store for later test	Comparative neutralization tests with both serums in tissue culture or suckling mice
	Same 10-14 days later (convalescent phase)	Separate serum	Comparative complement fixation tests

See page 394 for footnotes.

Table 62. Selection of Diagnostic Microbiologic Specimens (*continued*)

<i>Suspected Infection</i>	<i>Specimen</i>	<i>Handling of Specimen</i>	<i>Laboratory Tests</i>
<b>Nervous system</b>			
<b>Bacterial</b>			
<i>H. influenzae</i> Meningococcus Streptococcus Staphylococcus Pneumococcus Coliform bacilli Salmonella species Proteus species <i>Pseudomonas aeruginosa</i>	Nasopharyngeal swab	Place in 0.3 ml. of culture broth. <sup>1</sup> If stored, refrigerate <sup>9</sup>	Culture <sup>2</sup> and antibiotic susceptibilities Serologic typing*
	Cerebrospinal fluid	Sterile test tubes—in different tubes if there is a change in specimen. Examine at once or add 2 drops of 50% citrate if specimen is turbid	Cell count Microscopic examination of gram-stained smear. If clear, centrifuge first Sugar and protein estimation Culture of centrifuged specimen <sup>2</sup> and antibiotic susceptibilities Serologic typing*
	Blood, whole, 10 ml.	Add directly to culture medium. Place at 37° C.	Culture <sup>2</sup> and antibiotic susceptibilities Serologic typing*
Tuberculosis	Cerebrospinal fluid	Collect in sterile tubes—in different tubes if there is a change in specimen. If stored, refrigerate for fibrin web	Cell count Microscopic examination of Ziehl-Neelsen stained smear after centrifugation Sugar and protein estimation Culture (special method) of sediment
	See <i>Respiratory tract</i>		
Leptospirosis	Blood, whole, 2 drops from venipuncture needle	Add directly to 15 ml. of special culture medium. Do not refrigerate	Culture—special method (28°–30° C.)
	Cerebrospinal fluid	Add directly to special culture medium	Culture, as above Cell count Sugar and protein estimation
	Blood, whole, 5 ml.*	Collect in sterile bottle containing glass beads. Shake to defibrinate. Do not refrigerate	Culture as above, plus intraperitoneal injection of young hamsters
	Blood, clotted, 5 ml. (repeat in 4–7 days)	Collect in sterile tube and store in refrigerator	Antibody titer by agglutination-lysis method; <sup>10</sup> (preliminary, followed by repeat test with paired serums)
Fungus Cryptococcosis	Cerebrospinal fluid, tissue or exudate	Collect in sterile tube	Microscopic examination of wet India ink preparation of centrifuged sediment for <i>C. neoformans</i> Culture (special method) Inoculation of white mice

See page 394 for footnotes.

Table 62. Selection of Diagnostic Microbiologic Specimens (*continued*)

<i>Suspected Infection</i>	<i>Specimen</i>	<i>Handling of Specimen</i>	<i>Laboratory Tests</i>
Parasitic Toxoplasmosis	Cerebrospinal fluid	Collect in sterile tubes—different tubes if specimen changes. If stored, refrigerate	Cell count Microscopic examination of giemsa-stained smears of centrifuged material for <i>T. gondii</i> Intraperitoneal and intracerebral injection of mice and guinea pigs
	Blood, whole, 5 ml.	Collect in heparin. Examine at once or store in refrigerator	Intraperitoneal and intracerebral injection of young mice and guinea pigs
	Bone marrow or brain*	Collect in sterile tube. Refrigerate	Microscopic examination of stained smears and sections Animal inoculation
	Blood, clotted, 10 ml. (repeat in 1–2 weeks)	Collect in sterile tube	Complement fixation (paired serums). <sup>10</sup> Neutralization (dye) test <sup>10</sup>
Viral <sup>3</sup> Rabies Poliomyelitis Mumps ARBOR <sup>12</sup> viruses, including Eastern and Western equine, St. Louis, Japanese B, Murray Valley, Venezuela, California and many others Lymphocytic choriomeningitis (LCM) Herpes simplex Herpes zoster Coxsackie ECHO Cytomegalic inclusion disease	Brain or spinal cord	Take aseptically. Make contact smears. <sup>11</sup> Freeze small portions in dry ice	Examine for Negri bodies. <sup>11</sup> Virus isolation in animals or tissue culture
	Cerebrospinal fluid	Examine fresh. Freeze in dry ice	Cell count Sugar and protein estimation Virus isolation*
	Clotted blood, 5–10 ml. (acute phase)	Separate serum. Freeze clot in dry ice. Use some serum at once. Freeze and store remainder for later test	Virus isolation* Complement fixation test for mumps (See <i>Systemic infections</i> )
	Clotted blood, 5–10 ml. (convalescent 14–18 days)	Separate serum. Freeze and store remainder for later test	Comparative complement fixation tests with both serums against various neurotropic virus antigens
	Clotted blood, 5–10 ml. (late phase 6–8 weeks if indicated)	Separate serum	Comparative neutralization tests with all 3 serums in animals (especially for LCM)
Systemic infections Bacterial Typhoid fever Salmonellosis	See <i>Gastrointestinal tract</i>		
	Sputum*	Collect in sterile glass container. If stored, refrigerate	Culture (special methods) and antibiotic susceptibilities
	Swab of localized exudate*	Culture at once or place in 0.3 ml. of culture broth <sup>1</sup> and refrigerate	Same

See page 394 for footnotes.

Table 62. Selection of Diagnostic Microbiologic Specimens (*continued*)

<i>Suspected Infection</i>	<i>Specimen</i>	<i>Handling of Specimen</i>	<i>Laboratory Tests</i>
Brucellosis	Blood, whole, 10 ml.	Add directly to special culture medium. Place at 37° C.	Culture in 10% carbon dioxide Antibiotic susceptibilities Guinea pig inoculation*
	Lymph node biopsy*	Sterile tube. Divide into 2 portions, one for culture, the other for histologic examination. If stored, refrigerate	Same
	Blood, clotted, 5 ml. (repeat in 4-7 days)	Collect in sterile tube. Store in refrigerator	Agglutinin titers (preliminary, followed by repeat tests with paired serums)
Meningococcal, streptococcal, staphylococcal or pneumococcal With coliform bacilli, Proteus or Pseudomonas	See <i>Respiratory tract</i>		
Leptospirosis	See <i>Nervous system</i>		
Fungus Histoplasmosis	Peripheral blood, bone marrow aspiration and lymph node biopsy	Collect in sterile tubes containing heparin	Microscopic examination of thin and thick wright or giemsa-stained smears for intracellular parasites Culture—special method
	Swabs from ulcer, if available	Place in 0.3 ml. of sterile saline solution	Same
	Blood, clotted, 5 ml. (repeat in 1-3 weeks)	Collect in sterile tube	Complement fixation <sup>10</sup> (use paired serums for repeat test)
Parasitic Toxoplasmosis	See <i>Nervous system</i>		
Malaria	Blood, thin smears	Use thoroughly cleansed slides	Microscopic examination of giemsa-stained smears for plasmodia
	Blood, thick smears Sternal or splenic puncture*	Same Smear on clean glass	Same Same
Viral <sup>3</sup> Mumps Poliomyelitis Pleurodynia (Coxsackie B) Dengue Colorado tick fever Measles	Saliva	Freeze in dry ice	Virus isolation in eggs, suckling mice or tissue culture
	Stool		
	Blood, clotted, 5-10 ml. (acute phase)	Separate serum. Use some serum at once. Freeze and store remainder for later test	Complement fixation <sup>7</sup> test with soluble and viral mumps antigens
		Freeze clot in dry ice	Virus isolation in eggs, suckling mice and tissue culture
			Comparative complement fixation or neutralization test with both serums
	Blood, clotted, 5-10 ml. (convalescent 10-14 days)	Separate serum	
	Urine	Keep at 4° C.	Virus isolation in tissue culture
Cytomegalic inclusion disease

Table 62. Selection of Diagnostic Microbiologic Specimens (*continued*)

<i>Suspected Infection</i>	<i>Specimen</i>	<i>Handling of Specimen</i>	<i>Laboratory Tests</i>
<b>Rickettsial</b>			
Typhus fever group	Blood, clotted, 5–10 ml. (acute phase)	Separate serum. Freeze and store for later test. Freeze clot in dry ice	Guinea pig inoculation with clot for rickettsial isolation
Epidemic, murine and scrub typhus			
Rocky Mountain spotted fever			
Rickettsialpox	Blood, clotted, 5–10 ml. (convalescent 14–18 days)	Separate serum	Comparative complement fixation and agglutination tests with specific antigens, and Weil-Felix tests with both serums
Q fever			
Nonspecific reaction to streptococcal infection. Rheumatic fever and acute glomerulonephritis	Blood, clotted, 5 ml. (repeat in 7–10 days)	Collect in sterile tube. If stored, refrigerate	Antistreptolysin titer. Repeat with paired serums  C-reactive protein
<b>Urogenital tract</b>			
<b>Bacterial</b>			
Gonococcal	Cervical, vaginal and/or urethral swabs	Smear one on glass slides  Inoculate second swab directly to culture medium, or place in 0.3 ml. of culture broth <sup>1</sup>	Microscopic examination of gram-stained smear Culture <sup>2</sup>
Enterococcus Coliform bacilli Proteus species <i>Pseudomonas aeruginosa</i> Staphylococcus		Place in 0.3 ml. of culture broth. <sup>1</sup> If stored, refrigerate	Culture Antibiotic susceptibilities
<b>Syphilis</b>	Chancre fluid or scrapings from superficial lesions Blood, clotted, 5 ml. (repeat for confirmation)	Place in a few drops of saline. Examine at once Collect in sterile tube. Store in refrigerator	Darkfield examination  Microflocculation and complement fixation tests with cardiolipin antigen Treponemal tests for confirmation
	Cerebrospinal fluid*	Collect in sterile tubes— different tubes if specimen changes	Treponemal tests for confirmation Cell count Flocculation and cardiolipin complement fixation tests Colloidal gold
<b>Viral<sup>3</sup></b>			
Lymphogranuloma venereum	Scraping of lesion	Smear on glass slide	Microscopic examination of giemsa-stained smear for giant cells or elementary bodies
Herpes simplex	Pus from lesion or contents of vesicle	Place in sterile tube	
	Blood, clotted, 5–10 ml. (acute phase)	Separate serum, freeze and refrigerate for later test	Inoculation into animals, eggs or tissue culture
	Blood, clotted, 5–10 ml. (convalescent 14–18 days)	Separate serum	Comparative complement fixation tests with antigens of psittacosis—LGV group, with herpes simplex virus and neutralization tests with both serums
Cytomegalic inclusion disease	Urine	Keep at 4° C.	Isolation in tissue culture

See page 394 for footnotes.

<i>Suspected Infection</i>	<i>Specimen</i>	<i>Handling of Specimen</i>	<i>Laboratory Tests</i>
<b>Skin and mucous membranes</b>			
<b>Bacterial</b>			
Streptococcal and staphylococcal	Swabs from lesions.	Smear one on glass slide	Microscopic examination of gram-stained smear
With coliform bacilli, enterococci, <i>Proteus</i> and <i>Pseudomonas</i>	Cleanse skin with alcohol first	Place other in 0.3 ml. of culture broth. <sup>1</sup> If stored, refrigerate	Culture and antibiotic susceptibilities
<i>Fusospirochetal</i>	Swabs from lesions	Smear on glass slides	Microscopic examination of dilute carbolfuchsin-stained smears for <i>many</i> fusiform bacilli and spirochetes
<b>Fungus</b>			
Moniliasis	Swabs from surface of infected area	Use one swab to make smears on glass slide	Microscopic examination of gentian violet-stained smear for yeast cells
		Place other in sterile tube. If stored, refrigerate	Culture <sup>2</sup>
Blastomycosis Sporotrichosis	Swabs or scrapings from cleansed lesions	Place in sterile tube. Keep moist	Microscopic examination of wet lactophenol cotton blue mounts Culture (special methods)
Ringworm	Hairs or skin scrapings	Place in dry container	Microscopic examination of unstained preparation after clearing with 10% potassium hydroxide Culture (special methods)*
<b>Viral</b>			
Herpes simplex Herpangina (Coxsackie A) Variola Vaccinia Varicella Herpes zoster Molluscum contagiosum <sup>13</sup>	Vesicle fluid or swab	Place in nutrient broth and freeze in dry ice	Virus isolation in eggs, tissue culture or suckling mice
	Blood, clotted, 5-10 ml. (acute phase)	Separate serum. Freeze and store for later test	Comparative neutralization and/or complement fixation tests with appropriate antigens with both serums Histologic examination for inclusion bodies Microscopic examination of giemsa-stained smear for elementary bodies or giant cells
	Blood, clotted, 5-10 ml. (convalescent 10-14 days)	Separate serum	
	Biopsy	Fix in Zenker's acetic solution	
	Scraping of lesion	Smear on clean slide	
<b>Eye</b>			
<b>Bacterial</b>			
Streptococcal, staphylococcal, pneumococcal or gonococcal	Swabs of exudate from site of infection	Smear one on glass slide	Microscopic examination of gram-stained smear
		Place other in 0.3 ml. of culture broth. <sup>1</sup> If stored, refrigerate	Aerobic and anaerobic cultures on blood agar. Antibiotic susceptibilities

See page 394 for footnotes.

Table 62. Selection of Diagnostic Microbiologic Specimens (*continued*)

<i>Suspected Infection</i>	<i>Specimen</i>	<i>Handling of Specimen</i>	<i>Laboratory Tests</i>
<b>Viral<sup>3</sup></b>			
Trachoma <sup>13</sup>	Conjunctival scrapings	Smear on clean slide	Microscopic examination of giemsa-stained smear for inclusion bodies
Inclusion blennorrhea <sup>13</sup>			
Herpes simplex			
Epidemic keratoconjunctivitis (adenovirus type 8)	Swab	Place in nutrient broth and freeze in dry ice	Virus isolation in eggs, tissue culture or suckling mice
Variola			
Molluscum contagiosum <sup>13</sup>			
Varicella			
Herpes zoster	Blood, clotted, 5-10 ml.	Separate serum. Freeze and store for later test	Comparative complement fixation tests with various antigens and both serums
Newcastle disease	(acute phase)		
Pharyngoconjunctival fever (adenoviruses types 3, 7, 1)			
	Same after 10-14 days (convalescent phase)	Separate serum	Comparative neutralization tests with both serums*
<b>Wounds</b>			
<b>With</b>			
Pyogenic cocci	Swabs from infected	Smear one swab on glass slide	Microscopic examination of gram-stained smear
Anaerobic streptococci	wound		
Coliform bacilli		Place second swab in 0.3 ml. of culture broth. <sup>1</sup>	Culture <sup>2</sup> and antibiotic susceptibilities
Proteus species		If stored, refrigerate	
<i>Pseudomonas aeruginosa</i>			
Gas gangrene	Swabs from infected wound	Smear one swab on glass slide	Microscopic examination of gram-stained smear
		Place second swab in a tube of milk or thioglycolate medium and seal	Culture anaerobically
			Do toxigenicity tests in laboratory animals
	Pieces of débrided tissue	Place in sterile tube and refrigerate in case of delay	Examine ground-up tissue by stain and culture

\* Optional or not routinely indicated.

1. See Figure 104 (N-P culture outfit).
2. Aerobic and anaerobic blood agar plates are routine. Special culture media for coliforms, Salmonella and *Candida albicans*. Chocolate agar is the preferred medium for gonococci and meningococci; the cultures are incubated in 10 per cent carbon dioxide.
3. Incomplete list—includes viruses most likely to be encountered.
4. Myxoviruses include influenza A, B, C, D; mumps; Newcastle disease; hemabsorption viruses; and croup-associated virus (C.A.).
5. Respiratory syncytial virus or agent (chimpanzee-coryza agent—C.C.A.).
6. Include J.H. and 2060 viruses.
7. Valuable in an epidemic.
8. Sodium chloride, 0.45 gm.; K<sub>2</sub>HPO<sub>4</sub>, anhydrous, 0.3 gm.; potassium dihydrogen phosphate, anhydrous, 0.1 gm.; para-aminobenzoic acid, 5 mg.; glycerol, U.S.P., 30 cc.; distilled water, 70 cc.
9. Meningococcal and gonococcal specimens should be examined at once.
10. Tests carried out in specialized laboratories only.
11. For diagnosis of rabies.
12. Arthropod-borne virus.
13. Antigens not available.

should not be assumed that all hemolytic streptococci and staphylococci in a throat culture are pathogenic. Thus it is the responsibility of the laboratory to indicate, if possible, whether a potentially significant organism in some large heterogeneous category is likely to be pathogenic.

Under most circumstances isolation of a virulent bacterium or a virus from the patient provides highly suggestive evidence of an etiologic relationship and is usually accepted as sufficient for diagnostic purposes. Such a finding does not in itself, however, actually establish the organism as the cause of the

infection, and when there may be some doubt, further proof should be sought by serologic methods.

The demonstration of specific antibodies against the recovered agent in a single sample of convalescent serum, however, is not diagnostic. Unless it can be established that a rise in antibody titer occurred during the illness, the possibility must be considered that the patient is only an immune carrier who is suffering from an infection by a different pathogen. An antibody titer in convalescent serum (taken as a rule fourteen days or later after the onset of illness) which is at least fourfold greater than that found in the serum taken at the beginning of the illness is usually considered to be diagnostic.

Certain limitations of serologic methods should be mentioned. With most infections antibody is not detectable by ordinary methods during the first few days. When it does appear in blood, it may be directed toward a group or common antigen shared by many related microorganisms. This is the case with the psittacosis-lymphogranuloma group of viruses, the salmonellae, the rickettsiae of Rocky Mountain spotted fever and rickettsialpox, *Treponema pallidum* and *Histoplasma capsulatum*. Even a fourfold rise in titer in successive specimens may in reality be a booster or anamnestic response to an antigenically related but biologically unrelated organism.

Nevertheless serologic tests still provide val-

uable aid in establishing the etiology of infections. For example, a tentative diagnosis may be made on a *single* serum specimen under the following circumstances: (1) a high antibody level as compared with that of the population in general; (2) the presence of antibodies in the serum of a young infant which are not present in the mother's blood; (3) in mumps, antibodies to the soluble ("S") fraction of the virus, which often can be demonstrated as early as the second or third day of the disease, and before those to the viral ("V") antigen; (4) in typhoid fever the presence of Vi antibody.

## SELECTION OF ANTIMICROBIAL AGENTS BY LABORATORY MEANS

**General Considerations.** The great majority of bacterial infections can be cured without the use of the laboratory. For the remainder an effective therapeutic program requires the assistance of microbiologic procedures consisting of culture, identification of potential pathogens and determination of their susceptibility to chemotherapeutic agents.

Infections that need laboratory aid fall into three categories: (1) fulminating infections requiring hospitalization; (2) those which fail to respond to initial therapy; (3) those which relapse. For patients who are hospitalized for infections, bacteriologic specimens should be collected upon admission so

that, if clinical response to initially prescribed therapy is not satisfactory twenty-four hours later, the results of culture and susceptibility tests are available.

During recent years there has been a steady increase in the incidence of infections due to such bacteria as staphylococci, *Proteus*, *Pseudomonas* and enterococci which are often comparatively resistant, and sometimes completely so, to the commonly used chemotherapeutic agents. Whenever infections fail to respond to prescribed antimicrobial therapy, it is likely that the causative organism is resistant to the drug being used.

Relapses despite sustained medication result from the emergence of highly resistant

FIG. 105. Antibiotic susceptibility disk test on a nasopharyngeal culture containing a coagulase-positive *Staphylococcus* (large colonies) and a group A *Streptococcus* (small colonies). P, Indicates penicillin; S, dihydrostreptomycin; B, bacitracin; A, Aureomycin; C, Chloromycetin. Saline control disk is in the center. The *Staphylococcus* is resistant to penicillin and Chloromycetin, slightly susceptible to bacitracin, very susceptible to Aureomycin. Note streptomycin zone containing resistant colonies, indicating that this drug would probably be ineffective. The *Streptococcus* is very susceptible to Aureomycin, moderately so to penicillin and dihydrostreptomycin, and slightly so to bacitracin and Chloromycetin.

mutants or represent superinfections by secondary invaders, the most common of which are the four kinds of bacteria just mentioned. Relapses, whether due to resistant mutants or secondary invaders, constitute new infections which require further laboratory guidance.

Individual strains within the same species may vary greatly in susceptibility to a chemotherapeutic drug. This is true especially of strains of *Staphylococcus aureus* and members of the *Proteus* and *Pseudomonas* groups, so that susceptibility tests offer the only reliable basis for selecting the proper medication.

**Susceptibility Tests in Vitro.** These tests may be carried out in several ways, but the most useful methods are the disk-agar diffusion and the test tube-broth dilution tests. The latter is more accurate and can be applied to the evaluation of antibiotic combinations for synergism, but the test organism must first be isolated in pure culture, so that there is a delay of two or three days. Therefore its usefulness is mainly limited to subacute and chronic infections.

The disk test, on the other hand, can be carried out at the time of the primary culture; thus the results are available as soon as the

culture grows out. Disks may consist of compressed commercially prepared tablets, or pieces of impregnated paper (Fig. 105). Wet disks, soaked in a standard solution at the time of use, should be used only by laboratories qualified to establish adequate controls; on the other hand, commercial dry disks are satisfactory for use in any laboratory capable of culturing clinical material. Although the disk procedure is qualitative rather than quantitative, it selects the antimicrobial agents most likely to be effective. Disks carrying penicillin, streptomycin and a tetracycline should be used regularly. If further tests are indicated, pure cultures of the important isolated bacteria are used as inocula.

Commercial disks are available not only for antibiotics, but also for sulfonamides, isonicotinic acid hydrazide, p-aminosalicylic acid, Furadantin, Mandelamine and many other antimicrobial chemicals. The antimicrobial properties of the important chemotherapeutic agents appear in Table 63. Summarizations such as these, however, tend to be misleading because they imply that all members of a morphologic tinctorial category behave in the same way. One should keep in mind that important exceptions do occur. For example, the *Salmonella*, *Proteus* and *Pseudomonas* groups are generally resistant to the tetracyclines, although they are all gram-negative bacilli; and *Staphylococcus aureus* constitutes a group of gram-positive cocci for which susceptibility patterns vary in response to past exposure to antibiotics. *The need for susceptibility testing grows in proportion to the number of antibiotics being used.*

**Validity of susceptibility results in vitro.** Although the results as a whole correlate well with clinical experience, discrepancies occur. Many factors in the host, such as absorption, diffusion and excretion rate, may operate to diminish or increase effectiveness in vivo. The following factors may be responsible for clinical failure in a situation when "susceptible bacteria" had been reported by the laboratory: (1) absence of the causative organism among those isolated; (2) inadequate dose of the drug; (3) presence of resistant bacterial mutants; (4) replacement of the original susceptible flora by a more resistant one; (5) mechanical or anatomic barriers limiting access of the drug to the site of infection, such as a walled-off abscess or the valvular vegetations of subacute bacterial endocarditis.

Conversely, bacteria which appear to be resistant to a drug by the disk method, especially penicillin, may be rapidly destroyed

B = Usually effective.

in the patient's tissues. Clinical cures under such circumstances have become more frequent with the prescription of large doses of penicillin. The disk method measures only the bacteriostatic and not the bactericidal concentration, so that the effectiveness of penicillin, which, unlike other antibiotics, is rapidly bactericidal for many bacteria, is not completely reflected. The test tube-broth dilution test can be adapted to measure the bactericidal capacity of an organism, but the technique is not suitable for routine application.

Finally, microorganisms are not ordinarily destroyed in vivo by bacteriostatic drugs, whose role in clinical cure is to inhibit growth and thus increase the effectiveness of phagocytosis and other immune mechanisms; tests

in vitro do not measure the immunologic factor which operates in favor of the host.

## ISOLATION MEASURES FOR INFECTIOUS DISEASES

The care of a patient with a communicable disease involves measures to prevent others from contracting it, as well as treatment of the acute condition. Certain legal quarantine requirements, which vary somewhat in different localities, have been set up for the protection of the community (Table 64). Quarantine regulations have at best a limited value in control of the spread of contagious diseases. In many places "placarding" is no longer practiced for the so-called minor con-

tagious diseases, being used only for diphtheria, scarlet fever, smallpox, poliomyelitis and meningococcal meningitis. There are substantial arguments in favor of permitting children to contract such diseases as measles, German measles, chickenpox and mumps during the preadolescent years, provided they are in a state of good health at the time. For the control of diphtheria, smallpox and pertussis, artificially induced immunity is of greatest importance. However, a patient with

Table 64. Suggestions for Quarantine Regulations\*

<i>Disease</i>	<i>Patient Is Released from Isolation and May Return to School</i>	<i>Susceptible Contacts May Re-enter School</i>	<i>Immune Contacts May Re-enter School</i>
Diphtheria.....	On recovery, and after 3 successive negative cultures; or if avirulent. Not less than 16 days after onset if unable to obtain culture	When cultures of nose and throat are negative, but not for at least 7 days after last exposure	If bacteriologically negative
Scarlet fever.....	Upon recovery and cessation of purulent discharges; but not until at least 7 days from onset	Not less than 7 days after last exposure	If there is not continued exposure
Measles.....	On recovery; 9 days minimum (5 days after appearance of rash)	Exclusion from school of no practical value; when practised, at least 14 days must elapse after last exposure	No restriction
German measles..	Quarantine is usually not imposed. Period of infectivity estimated from 3 to 5 days after onset of catarrhal symptoms	Exclusion from school of no practical value; when practised, at least 21 days must elapse after last exposure	No restriction
Smallpox.....	On recovery and disappearance of scabs and crusts; usually 3 to 6 weeks	18 days after successful vaccination	If there is not continued exposure and if successfully vaccinated within 5 years. The person should be vaccinated whenever exposure occurs even if there has been a previous successful "take"
Chickenpox.....	On recovery and when crusts have formed; at least 7 days after onset	Exclusion from school of no practical value; when practised, at least 21 days must elapse after exposure	No restriction
Pertussis.....	Not before 3 weeks after onset of typical paroxysms	14 days after exposure	No restriction
Poliomyelitis.....	One week after onset of symptoms or after defervescence, whichever is longer	2 weeks	2 weeks
Mumps.....	When swelling has disappeared	Usually no exclusion. Regular, daily inspection advised	No restriction

\* Adapted from several sources, principally from The Control of Communicable Diseases, The American Public Health Association, New York, 1945, and Report of the Committee on Immunization and Therapeutic Procedures for Acute Infectious Diseases, American Academy of Pediatrics, 1952.

a contagious disease should be isolated, not only to limit distribution of the disease, but also to protect him from secondary infection.

Isolation technique necessitates cooperation of physician, nurse and family, and, in hospitals, of all personnel, including orderlies and maids, who come in contact with the patient or his environment. An error in technique by any one of these persons may defeat the efforts of all the others.

The patient is regarded as a contaminated unit, and the area in which he is—whether a room in home or hospital, a cubicle or space in a ward—as a contaminated unit area. The space between beds in an open ward should be at least 6 feet. Anything which comes in contact with the unit area must be consid-

ered contaminated. Isolation precautions for persons entering and leaving the unit area are based on "hand and gown technique"; all physicians and nurses should be familiar with an approved method. When the child is to be cared for by a nonprofessional attendant at home, as, for example, the mother, adequate instruction should be given by the physician.

Infectious agents may also be transferred to another person by air conduction. The control of air-borne infection has received considerable attention, but is still not adequately solved for practical application. Oiling of floors and of bed blankets would appear to be as useful a method as any; air sterilization with ultraviolet irradiation or an aerosol has a limited effectiveness in reducing the

spread of infection in institutions. Antibiotic treatment of bacterial infections is the most effective means for limiting their spread.

The unit area must be properly equipped to care for the patient, and nothing should be taken into it that is not necessary or cannot later be destroyed or sterilized in some manner. The trays and dishes—or the bottles for infants—should be sterilized after each use by boiling or autoclaving.

A bedpan should be provided for each patient, or bedpans should be sterilized. In the home a special bathroom reserved for the isolated area is a great convenience.

Bed linen and clothing, including diapers, should be sterilized in an autoclave; in the home they should be boiled before being sent to the laundry.

Secretions from the eyes, nose, mouth and throat should be received on soft paper squares or small pieces of cloth which are placed in a paper bag and later burned.

All attendants should be in good health and free of infection of the respiratory tract.

The patient should be discharged from the unit area only after thorough bathing with soap and warm water, including a shampoo.

He should not, of course, return to the contaminated area.

Other materials, as well as the floor and furniture of the room, should be thoroughly washed with soap and water, and the room aired for at least twenty-four hours before again being occupied.

Material in the unit area which cannot be burned is cleansed as follows: all clothing and linen, as already described; mattresses and pillows are aired for six to eight hours, preferably on two successive days; all glass, rubber, chinaware, enamelware and any instruments which permit it are boiled for five to ten minutes, or autoclaved, or put into 2 per cent cresol solution or 1:5000 Zephiran for eighteen hours.

When a patient is to be taken to an operating room or x-ray room, or is transferred to another unit area, the accompanying attendant must wear a clean gown, and the patient should wear a mask and must be wrapped in a clean sheet. Equipment in the operating or x-ray room which has been contaminated should be cleaned in the manner described for the unit area.

Table 65. Résumé of the Common Contagious Diseases Having an Exanthem or Enanthem

	Diphtheria	Scarlet Fever	Measles	German Measles	Smallpox	Chickenpox
Etiology	<i>Corynebacterium diphtheriae</i>	Hemolytic Streptococcus (Group A; some symptoms perhaps allergic)	Virus	Virus	Virus	Virus
Transmission	Usually direct contact; by carriers	Usually direct contact; occasionally indirect or by contaminated milk, etc.	Usually direct contact	Direct contact	Direct or indirect contact; probably air-borne	Direct or indirect contact; probably air-borne
Incubation	2-5 days	2-7 days	10-14 days	14-21 days	8-16 days	14-21 days
Mouth and throat	Pseudomembrane spreads beyond tonsillar area and is difficult to remove	Punctate scarlet enanthem; tonsillar exudate; strawberry tongue early; raspberry tongue later	Koplik's spots	Macular eruption on soft palate (Forchheimer's spots)	Lesions on mucous membranes	Vesicular enanthem
Eruption	None	Bright red, punctate; face little involved; first on neck and chest, then spreads downward; later (after a week), desquamation, especially of hands and feet	Reddish maculopapules, centrally grouped, appear first on face; later (after a week), branny desquamation	Pale rose macules, variable in size, discrete; first on face, spreads rapidly (24 hours) over body. At times scarlatiniform rash	Macules, then papules, then vesiculation of papules, then (by sixth day) pustules. Attacks first face and wrists, then hands and arms, then trunk and legs (chiefly on exposed parts of body)	Macules, papules, then vesicles, then some become pustules; lesions superficial, and found simultaneously in all stages of development. Attacks first face and back, then spreads rapidly downward (chiefly on covered parts of body)
Important constitutional symptoms	Fever often not high; marked prostration	At onset: sore throat, fever, nausea or vomiting and headache	Photophobia; catarrhal symptoms. Fever may subside about third day of invasion, then recur within 24 hours when the rash appears	Mild catarrhal symptoms; slight fever; may be none	At onset: vomiting, headache, high fever. Improvement at onset of rash; fever again in pustular stage	Fever; usually slight general reaction
Blood	Polymorphonuclear leukocytosis usually not very marked	Leukocytosis even if not marked, always a polymorphonuclear increase	Absence of leukocytosis; neutropenia common	Absence of leukocytosis	May be leukopenia in prodromal stage; later leukocytosis, often with mononuclear increase	Slight leukocytosis
Important complications	Bronchopneumonia; cardiac failure; postdiphtheric paralysis	Otitis; adenitis; arthritis; nephritis; enditis	Bronchopneumonia; otitis media; sinusitis; laryngitis; encephalomyelitis	Occasionally bronchopneumonia; encephalomyelitis	Laryngitis, bronchopneumonia; gangrene; encephalomyelitis	Pustular skin lesions; encephalomyelitis
Diagnosis: Technical aids	By culture from membrane	Culture; Schultz-Charlton test				
Other features	May be nasal or laryngeal involvement, etc.	"Surgeal" scarlet fever	Risk to fetus in first trimester	May be modified by previous vaccination		

# BACTERIAL INFECTIONS

## STREPTOCOCCAL INFECTIONS

### GENERAL CONSIDERATIONS

Most human and animal streptococcal infections are caused by beta-hemolytic streptococci, which produce a brilliant, complete hemolysis of blood. The viridans and non-hemolytic streptococci are of relatively low virulence and most often exist in the throat or feces, unassociated with disease. When they produce infection, it is usually subacute or chronic.

The beta-hemolytic streptococci are divided into groups, designated A through N, and these groups have distinct host associations. Group A streptococci are most commonly associated with infections in man, group B with cattle, and group C with cattle, horses, guinea pigs and other animals. Groups C, D and G are occasionally and groups B and F rarely pathogenic for man. Table 66 shows these and other host relationships.

**Cellular Antigens of Group A Streptococci.** The various groups of beta-hemolytic streptococci are differentiated in the laboratory by means of a precipitin test involving the C-substances, which are complex polysaccharides immunologically distinct in each group. The group A streptococcal cells contain protein antigens designated by the letters M, T, P and R. Of these, the M-substance is most important, since it determines the type-specificity of group A strains.

More than forty streptococcal types have been described. The streptococci that cause acute infections of the throat and elsewhere, including the infections associated with scarlet fever and those preceding rheumatic fever, may belong to any of the types. Rammelkamp and his associates have presented evidence that certain strains of streptococci, particularly type 12, produce infections complicated by acute glomerulonephritis more frequently than do strains of other types.

The M-substance appears to be related to the virulence of the organism; the antibodies it evokes are responsible for type-specific immunity. The T-substance is a type antigen of secondary importance, since it is not involved in virulence or protection. The P-antigens are nonspecific, being present in many gram-positive organisms. Little is known of the significance of the R-antigen, which is present in only a few streptococcal strains.

**Extracellular Antigens of Group A Streptococci.** The *erythrogenic toxin*, produced by about 90 per cent of group A streptococci, is responsible for the rash and possibly for other toxic manifestations of scarlet fever. Only strains producing erythrogenic toxin are capable of causing scarlet fever. Streptolysins O and S are the two hemolytic toxins of group A streptococci. They are distinct chemical entities with distinct toxic properties. Most strains of group A streptococcus produce both

\* From R. C. Lancefield, Harvey Lecture, 1940-41.

lysins, but occasional strains fail to produce one or the other. Streptolysin O causes myocardial damage in experimental animals and also has an injurious effect on leukocytes. Streptokinase (fibrinolysin) activates a proteolytic enzyme, plasminogen, normally present in blood, which causes dissolution of fibrin clots. It is not pharmacologically toxic, but may play a part in the spread of streptococci through tissues by activating the destruction of fibrin barriers. The *proteinase* of Elliott is an enzyme produced by certain strains of group A streptococci which digests many proteins, including the type-specific M protein in culture. Streptococcal *hyaluronidase* attacks the hyaluronic acid of the capsule of group A streptococci as well as the same polysaccharide found in such tissues and fluids as Wharton's jelly, joint fluid and connective tissue; other streptococcal enzymes include *desoxyribonuclease* and *diphosphopyridinenucleotidase*, the latter possibly being responsible for the leukotoxic action of certain streptococci.

**Antibodies to Streptococcal Antigens.** In natural and experimental infections, antibodies directed toward the various intracellular and extracellular antigenic constituents of streptococci appear in the blood. Of the cellular antigens of the group A *Streptococcus*, those provoked by the M-antigen are the most important. They are type-specific and constitute a main factor in immunity to reinfection of the human host. Infection with a particular type of *Streptococcus* is believed to produce type-specific immunity which lasts for many years. Antibodies for the M-antigen in serum cannot be measured by the precipitin reaction, but indirect evidence of their presence is provided by a phagocytic test. Anti-M bodies appear in the human host as early as three weeks after the onset of natural infections and persist as long as three years. Watson showed that after infection with a particular type of group A *Streptococcus*, a monkey was immune to reinoculation with the same type for at least a year, but could readily be infected with strains belonging to other types.

Antibodies for the T-, P- and R-substances are not practicably measurable in human serums after infection.

Antibodies for the erythrogenic toxin are responsible for lasting immunity to the rash of scarlet fever. Their presence in the human host is measured by the Dick test. Antibodies for streptolysin O, antistreptokinase and hyaluronidase have been widely used, because they indicate a previous streptococcal infection, even though the infecting organisms may

have disappeared from the host. Antibodies to these three substances usually reach higher levels in the blood of rheumatic fever patients than in the blood of patients having uncomplicated streptococcal disease, and their presence is one of the strongest pieces of evidence supporting the streptococcal etiology of rheumatic fever.

**Drug Susceptibility and Resistance.** With the exception of group D organisms, most beta-hemolytic streptococci are susceptible to low concentrations of the sulfonamides, penicillin, tetracycline, chloramphenicol and erythromycin. Penicillin is at present the drug of choice for streptococcal infections. Some strains of group D streptococci are sensitive to streptomycin.

The acquisition of resistance to these drugs has been a problem only with the sulfonamides, and such evidence is largely limited to experience in military camps during World War II. Sulfonamide-resistant strains are rare in the general population. Recently tetracycline-resistant group A strains have been encountered.

**Epidemiology.** Climate influences the prevalence of streptococcal disease, the colder climates generally showing a higher incidence; in any climate streptococcal infections are most common in the winter and in spring. Strains isolated during epidemics almost always belong to group A, contain large amounts of M-substance and are mucoid and encapsulated. However, many strains with these same characteristics show little tendency to spread at epidemic rates. It is impossible to distinguish epidemic from nonepidemic strains with certainty by laboratory tests.

In some instances the mode of dissemination of the infecting organism influences an epidemic. The chief natural reservoir of group A streptococci is the human upper respiratory tract, and spread from infected persons or carriers to susceptible persons is largely by direct contact or through air. It is likely that spread in the course of relatively intimate human contact, by either direct mechanical transfer or the transmission of large infected droplets, is more dangerous than spread over longer distances by small infected particles. Streptococci in dust are incapable of inducing infections in human volunteers.

Epidemics resulting from milk-borne spread of cocci were once common, but have not been encountered recently in this country. This may largely be attributed to widespread pasteurization of milk. Only rarely do epidemics result from direct contamination of

raw milk by a dairyman or food handler, because milk contains a substance, lactenin, which prevents the growth of group A streptococci. Streptococci grow well in reconstituted, dried or canned milk and in milk sterilized by heat, since the lactenin is thus destroyed; epidemics have occurred after direct contamination of such milk. Thus, since the presence of only group A organisms is of significance in milk, the importance of serologic grouping of streptococci from a suspect milk supply during an epidemic of streptococcal disease is obvious.

The composition of the community affects the course of epidemics. In a large urban area where the number of susceptible persons may be relatively small and widely scattered and intimate human contacts are limited, the increase in number of cases may be slow and irregular and may continue at a fluctuating low epidemic level for a long time until immunity becomes general or until seasonal influences interrupt the course of the epidemic. In a closed or semiclosed community, such as a boarding school or an orphanage, where contacts are close, the attack rate rises rapidly to a peak and tends to terminate rapidly.

In military training centers a different epidemic situation may exist. Here the transfer of infection is facilitated by close contact and by the introduction of new susceptibles at frequent intervals. After the initial rise the attack rate continues to be irregularly high instead of falling off.

An important and familiar type of epidemic is that which occurs in hospitals (nosocomial infections). They may be epidemic, but more often are sporadic. Premature infants and other malnourished, debilitated, eczematous, syphilitic or mentally defective infants who remain in the hospital for prolonged periods are most prone to acquire nosocomial infections. The sources of infection are hospital personnel, visitors and fellow patients.

Another hazardous situation exists in the waiting rooms of busy physicians, although the period of exposure is relatively brief.

#### CONTROL MEASURES

Measures for the control of streptococcal infections are (1) attempts to prevent exposure of susceptibles, (2) avoidance of environmental conditions which favor epidemic spread of infection, (3) attempts to render the host insusceptible to the organism.

To prevent exposure of susceptibles it is customary to isolate known infected persons.

Isolation and quarantine procedures are inadequate because many infections are transferred by mild or undiagnosed cases and by carriers, whom it is not feasible to isolate. The arbitrary periods of isolation of seven to twenty-one days for patients with scarlet fever have no sound basis. The segregation of patients with scarlet fever in so-called group isolation is to be decried, since patients infected with one serologic type can acquire infection of a different type from a neighboring patient.

Because patients may carry streptococci for months and sometimes for more than a year, it is not practical to isolate all convalescent patients carrying streptococci until negative cultures are consistently obtained. Only patients carrying group A streptococci are potentially dangerous, but some carriers of group A organisms are more efficient disseminators of infection than others. Patients with large numbers of streptococci in their anterior nares are especially dangerous. In such cases it might be advisable to try to eradicate the carrier state with massive doses of penicillin.

To minimize the occurrence of cross infections in hospitals, McKhann makes the following recommendations: Infants and other particularly susceptible patients should be hospitalized only when absolutely necessary, and the stay should be as short as possible. Infected patients should be isolated from non-infected ones and from one another. Open cubicles with walls not reaching to the ceiling are less satisfactory for this purpose than cubicles with walls extending to the ceiling; these in turn are less effective than separate rooms with individual outside ventilation. Visiting should be restricted to the immediate family. "Hand and gown" technique and the use of deflecting or filtering masks help to reduce spread from one patient to another and from attending personnel to the patient; but no matter how diligently they are used, they are inadequate to prevent all cross infection.

The pasteurization of milk, the proper preparation and handling of food and the elimination of infected persons and carriers from the kitchen are measures used to prevent food-borne streptococcal infections.

Vaccines for immunization against streptococcal infections have not been successful; this fact is not surprising, since immunity to streptococci is largely type-specific. Because of the large number of serologic types, active immunization could be profitably used only in epidemics in which the infecting strains would be typed early and immunity to these

particular types conferred. Immunization with the Dick toxin has been used under special circumstances—for instance, among student nurses. It prevents only the rash of scarlet fever and not the acquisition of streptococcal infection. As a general procedure it is not recommended.

*Chemoprophylaxis* with a sulfonamide or penicillin has been used for the prevention of streptococcal infection in individuals and for the interruption of streptococcal epidemics in groups. Its use in the individual patient has been studied most extensively in children who have had an attack of rheumatic fever and for whom streptococcal infections constitute a serious hazard (see p. 910 for details).

Because of the hazard of subacute bacterial endocarditis developing when teeth are extracted or tonsils removed, penicillin should be given to patients with rheumatic heart disease before and after such operations.

#### SCARLET FEVER

(SCARLATINA)

**Definition.** Scarlet fever is an acute infection caused by a member of the group A beta-hemolytic *Streptococcus*. The clinical picture is a combination of septic and toxic manifestations. The primary site of infection is usually the pharynx, from which the organism may invade surrounding tissues and even the blood stream. The organism produces a potent soluble toxin, which, after absorption into the blood stream, causes such symptoms as fever, headache, delirium, rapid pulse, vomiting and the rash. Some of the clinical manifestations have been regarded as allergic. The hemolytic *Streptococcus* is responsible for a variety of clinical diseases, such as tonsillitis, otitis media, meningitis and erysipelas, which from an epidemiologic standpoint should be considered on the same etiologic basis.

**Etiology** (see also p. 401). Any erythrogenic toxin-producing strain of beta-hemolytic *Streptococcus* may cause scarlet fever. Actually these are all members of group A with the

exception of a few in groups C and G. Strains of the organism are serologically assigned to a group on the basis of their group antigen, the C-substance, which is a carbohydrate. Within a group many different types exist, recognized on the basis of their M-substance, which is a protein.

One or more types of the group A organism may be identified as the causative agent in a given outbreak of the disease. In one outbreak twenty-two different types were encountered among 228 patients. Of these, the most frequently observed types were 14, 18, 28 and 3.

Group A organisms elaborate a number of soluble substances, some of which are important in pathogenesis. These are the erythrogenic toxin, streptolysins (O and S), fibrinolysin (streptokinase), leukocidin and hyaluronidase. The rash-producing toxin is one of the most important and may exist in the blood in a concentration of 30 to 300 units per milliliter within eighteen hours of the onset of illness. During convalescence, or after active immunization with toxin, specific antitoxin develops and the Dick test reverses from positive to negative.

**Epidemiology.** Serologic typing and grouping have greatly enhanced knowledge of factors influencing the existence and spread of streptococcal infections. Within a given community the flora may consist of many different types, constantly changing in occurrence and dominance. Obviously, the carrier state is important and causes the major portion of infection by direct contact. In close quarters air-borne transmission is highly probable.

The carrier rate and the incidence of scarlet fever are influenced by season. Late fall, winter and early spring are the seasons of highest incidence. The disease is common in temperate and cold climates; rare in tropical areas, although the Dick-negative distribution within age groups in tropical areas resembles that in the temperate areas. Negroes, Eskimos and the yellow race appear to possess natural immunity. In the United States the disease is most common in the North, including the Rocky Mountain States, and least frequent in the South.

About half of the cases of scarlet fever occur between the ages of two and eight years, although other types of streptococcal infection in early infancy are not unusual. Certain families appear to be particularly susceptible, but the family communicability rate is only 5 to 10 per cent.

Both the morbidity and mortality rates in the United States have markedly decreased

in the last twenty years. For example, in New York City there were 50,622 cases reported during the period 1935–1939 with a fatality rate of 0.4 per cent. During the period of 1951–1954, 9430 cases were reported with a fatality rate of 0.01 per cent.

**Immunity.** Resistance to scarlet fever is both antibacterial and antitoxic. Antitoxic immunity is the more important, since it provides protection, usually permanent, against the erythrogenic toxin, which is responsible for the rash. Antibacterial immunity is type-specific. Though immunity to a given strain of *Streptococcus* may be of long duration, repeated streptococcal infections such as tonsillitis, sinusitis and otitis media are the rule, each possibly being an infection with a different strain. The presence of antitoxic immunity (negative Dick reaction) would seem to account for the occurrence of "scarlet fever" without an eruption (*scarlatina sine exanthemata*).

Immunity to the erythrogenic toxin is measured by titrating the serum and is reflected within limits by the Dick test.

This skin test consists in injecting 0.1 cc. of standardized streptococcal toxin intradermally. The amount of toxin injected is the amount which will produce within eighteen to twenty-four hours an area of erythema at least 1 cm. in diameter in the susceptible subject. This is known as one skin test dose (S.T.D.). The test is usually positive during the first few days of the disease and negative during convalescence. The test is more dependable with the heat-

labile toxin than with the ordinary Dick toxin. The heat-labile toxin is obtained from ordinary toxin by precipitation with alcohol (Ando). The heat-stable fraction accounts for the occurrence of a number of the Dick-positive reactions observed during convalescence.

The relation of the incidence of positive Dick reactions to age is similar to that of the Schick test (Fig. 106). During the first three to six months of life the Dick test is negative in the majority of infants, but this finding is not explained by the presence of demonstrable antitoxin in the blood.

*Passive immunity* may be conferred in a susceptible person by the injection of suitable amounts of convalescent serum, of whole blood from an immune donor or of antistreptococcal serum. It is difficult to assess antitoxic immunity, which probably fluctuates. Moreover, there is evidence that erythrogenic toxins are heterogenic, a fact that may explain variations observed in skin testing.

*Active immunity* is conferred by an attack of the disease or by a series of injections of toxin. It is probably also produced by repeated unrecognized infections by toxigenic strains of hemolytic streptococci.

**Pathology.** The local lesions result from bacterial invasion and consist of acute tonsillitis and pharyngitis. The tonsils are enlarged and hyperemic, and their crypts are filled with exudate. The mucous membrane of the pharynx is hyperemic and edematous. An

FIG. 106. Relation of age to the incidence of positive Dick reaction. (F. F. Schwentker, J. H. Janney and J. E. Gordon: *Am. J. Hyg.*, Vol. 38.)

infiltrate of polymorphonuclear leukocytes is present in the edematous submucosa as well as within the epithelium; the latter is covered by patches of mucopurulent or fibrinopurulent exudate. The regional lymph nodes are enlarged and reveal toxic hyperplasia or sup-puration.

The exanthem and enanthem are the result of bacterial toxins. Hyperemia of the corium is responsible for the diffuse redness. In addition, there is edema of the skin with a lymphocytic and monocytic infiltrate around the hair follicles. The cellular and fluid exudate accumulates in the midzone of the epidermis, where an accelerated keratinization (pseudo-keratosis) occurs. Separation of the outer layers of the epidermis from the intermediate keratinized zone is responsible for the des-quamation. The "strawberry" appearance of the tongue results from erythematous papillae projecting from a gray-coated background; with desquamation a beefy red appearance ensues.

Visceral involvement consists in general-ized hyperplasia of lymphoid tissue and perivascular and diffuse infiltration of lymphocytes and monocytes. These infiltrates are especially prominent in the heart, liver and kidney; in renal interstitial tissue they may rarely lead to uremia, which usually appears within a week after the eruption.

**Clinical Manifestations.** The incubation period is usually two to four days, with an upper limit of six to seven days.

The primary infection, which occurs in the pharynx, is responsible for the toxic mani-festations and for the septicemia. The toxic manifestations include headache, fever, vom-iting, rapid pulse, delirium, exanthem, enan-them, generalized lymphadenitis, myocarditis, nephritis and perhaps arthritis. The septic manifestations resulting from bacterial inva-sion of the tissues and blood stream, in addi-tion to cellulitis of the pharynx and neck, and cervical adenitis, may include otitis media, sinusitis, mastoiditis, pyelonephritis, endocarditis, meningitis and other metastatic lesions.

The typical case of scarlet fever begins with headache, fever, sore throat and vomiting, followed within twenty-four to seventy-two hours by the appearance of the rash.

The onset is sudden, with a temperature of 101° to 104° F., reaching its height about the second day and gradually subsiding to normal by the seventh to the tenth day. The pulse rate is increased out of proportion to the temperature. Nausea is common, and

vomiting occurs in approximately 80 per cent of the cases in children. Headache is often severe, and prostration is common.

The throat is deeply injected (Fig. 107), and petechiae are present on the uvula and soft palate. Edema of the soft tissues may be present. Mucopurulent exudate may be dis-tributed over the surface of the tonsil, re-sembling the early lesion of diphtheria. In severe cases a serosanguineous nasal discharge may be present. The cervical lymph nodes are usually palpable, often definitely enlarged and tender. There is also a generalized en-largement of the superficial lymph nodes.

The eruption is a diffuse, finely papular, bright red erythema which blanches on pres-sure. It begins twelve to seventy-two hours after the onset of symptoms about the base of the neck, in the axillae and groins, and later appears on the trunk and extremities. The cheeks are flushed, and a ring of pallor corresponding to the topical area of the orbic-ularis oris muscle encircles the mouth (cir-cumoral pallor). Invasion of this area by a true exanthem does not occur, and frequently the remainder of the face is also spared. When there is a rash over the cheeks, it is of less degree than elsewhere. In the creases on the flexor surface of the elbow are deeply injected transverse lines of hyperemia which do not fade on pressure (Pastia's sign, Fig. 108). Petechiae are frequent in the more toxic cases and may occur in mild cases; the Rumpel-Leede test is positive.

The toxic eruption may be locally blanched by the intradermal injection of 0.2 ml. of convalescent serum or diluted commercial antitoxin. This reaction, considered to be a local neutralization of the erythrogenic toxin by specific antitoxin, is known as the Schultz-Charlton blanching phenomenon (Fig. 109). A circumscribed area of blanching appears within eight to twenty-four hours at the site of injection. A positive reaction is strongly indicative of scarlet fever; a negative reaction does not rule out the disease, possibly be-cause of the existence of more than one type of erythrogenic toxin. The test is rarely posi-tive after the fourth day of the disease.

After three to seven days the rash fades and is followed by a branny type of desquama-tion (Fig. 110) which is most noticeable in the axillae, groin, finger tips and at the base of the nails, but may occur anywhere on the body. The degree of desquamation is propor-tional to the intensity of the rash. In mild cases it may be absent.

The so-called strawberry tongue is observed

in more than half of the cases and is an important clinical sign. Early in the disease the tongue is coated and somewhat swollen, the borders and tip are deeply injected, and the papillae are prominent (white strawberry tongue, Fig. 111). By the third or fourth day the coating desquamates, leaving a beefy red tongue with swollen papillae (red strawberry tongue) (Figs. 112, 113). This type of tongue is frequently observed in streptococcal infections without eruptions.

The clinical patterns of scarlet fever vary markedly in severity. The more toxic or septic the initial reaction is, the more frequent and numerous are the complications and the more grave is the prognosis.

There is usually a secondary anemia, albuminuria and leukocytosis. The white blood cell count is 10,000 to 20,000, of which 75 to 90 per cent are polymorphonuclear cells. Eosinophilia (4 to 20 per cent) may be observed after the fourth day of the rash. It diminishes during the second week and often increases again during the third week.

Relapses occur in about 0.5 per cent of cases in the third to sixth week of the disease and are now generally regarded as representing infection with a new strain of *Streptococcus*. They are usually of shorter duration and less severe than the original attack, and their occurrence may be influenced by such factors as inadequate antibiotic therapy and failure of the host to develop antitoxic immunity.

Second attacks are rare and require clinical and bacteriologic proof. The few instances of suspected second attacks observed by the author usually occurred in allergic persons, and confirmatory evidence of one of the attacks was incomplete. Diagnosis of second attacks on clinical evidence alone is not reliable.

**Differential Diagnosis.** The typical case offers little difficulty in diagnosis. The characteristic onset with fever, sore throat and vomiting followed within one to three days by a diffuse erythematous rash constitutes a presumptive diagnosis of scarlet fever. In mild, atypical cases and in infants the diagnosis may be exceedingly difficult.

In *German measles*, which is perhaps most frequently confused with the mild type of scarlet fever, the intensity of the eruption is out of proportion to the symptoms. Enlargement of the occipital nodes and the rapidly changing and fading eruptions are characteristic. The throat symptoms are mild, and desquamation is rare.

*Measles* can usually be identified by the catarrhal symptoms, the morbilliform erup-

tion with involvement of the face, the presence of Koplik's spots, and leukopenia. The modified type of measles may offer considerable difficulty in diagnosis.

*Exanthema subitum* may on occasion present an eruption more scarlatiniform than morbilliform. The course of the disease and leukopenia are characteristic.

*Infectious mononucleosis* may be differentiated by serologic and hematologic data.

*Drug rashes*, particularly those caused by belladonna, the coal-tar derivatives, sulfonamides and irritants to which the patient is allergic, are common causes of error. Drug rashes are usually more intense on the extremities. The history of drug administration is helpful. The scarlatiniform type of eruption associated with serum disease is easily identified by its pruritic quality and its relation to an injection of serum.

When the throat symptoms in scarlet fever are severe and the eruption is not characteristic, the throat culture, history of active immunization and the Schick test may assist in ruling out *diphtheria*.

In general, the following evidence may assist in the positive diagnosis of a questionable case of scarlet fever: (1) history of exposure within one week; (2) concurrent streptococcal infections in siblings or close contacts; (3) subsequent desquamation or development of nephritis; (4) many hemolytic streptococci in the throat culture; (5) positive rash-extinction test; (6) reversal of the Dick reaction during the illness.

**Complications.** The complications fall into two general groups: (1) those caused by septic infection by the hemolytic *Streptococcus* or other secondary invading organism, and (2) those caused by the toxin.

The incidence of the septic complications, suppurative cervical adenitis, sinusitis, otitis media, mastoiditis, lateral sinus thrombosis, epidural abscess, meningitis and endocarditis, has been greatly reduced by early treatment with effective antibacterial agents.

*Sinusitis* probably occurs in most cases, varying from a mild ethmoidal infection to severe pansinusitis. Definite cellular reaction of the orbital tissues is commonly associated with ethmoidal infection. Persistent purulent rhinitis is indicative of sinus infection, which often remains as a focus in the carrier state. The tonsils and adenoids are always infected and frequently are responsible for persistence of the nasal infection. The presence or absence of tonsils and adenoids has little to do with the incidence of scarlet fever. Retro-

pharyngeal and peritonsillar abscesses are also complications.

The pain of acute *mesenteric adenitis* may resemble that of appendicitis.

*Laryngitis* is occasionally an early manifestation and may be obstructive. It may progress to diffuse laryngotracheobronchitis.

*Bronchopneumonia* is not common and is usually interstitial in type; empyema develops in about one third of untreated cases.

*Cardiac disorders*, which are of several types, occur in less than 1 per cent of cases. One of the most common is acute toxic myocarditis, which occurs early and is not unlike that of diphtheria. It is often transient. Bacterial endocarditis and pericarditis are septic in origin. If rheumatic carditis occurs, it usually does so during the second or third week.

*Albuminuria* with only an occasional cast or red blood cell occurs early in most severe cases. It usually disappears when the temperature subsides.

Clinically manifest acute *glomerulonephritis* occurs in about 1 per cent of cases in the second or third week of the disease. As shown by Lyttle, an increase of urinary protein and cellular components may be found in the majority of cases at this time, if studied by the Addis method.

*Arthritis*, usually involving the smaller joints, may occur in older children during the second or third week of the disease. It is probably caused by the toxin and subsides within a week or more. It resembles rheumatic fever, which may also occur at this time. Suppurative arthritis of pyemic origin is usually multiple and involves the large joints.

*Paronychia* is a common minor infection.

**Prognosis.** The mortality rate in the United States is now under 1 per cent. It is somewhat higher in infants, in whom septic features of the disease are more common. These complications should be controlled by early and adequate antimicrobial therapy. Late complications such as rheumatic fever and glomerulonephritis may occur regardless of the severity of the disease.

**Prevention.** Isolation measures have in general failed to control the spread of scarlet fever, owing to the many sources of group A beta-hemolytic streptococci. The carrier rate appears to be little affected by quarantine.

Patients adequately treated with penicillin for ten days rarely become carriers. If the mucous membranes of the nasopharynx appear normal and there are no purulent com-

plications, isolation of the patient may be discontinued after seven days.

Exposed persons, especially family contacts, may be effectively protected by oral administration of 200,000 units of penicillin night and morning for a week after exposure. Exposed persons who have had rheumatic fever should receive adequate prophylactic therapy.

Since active immunization with toxin results only in prevention of the rash, but not of the infection, it is not recommended.

**Treatment.** Rest in bed, adequate fluids, and a liquid, soft or regular diet, as the child desires, are the general measures indicated in the acute stage. Codeine and aspirin may be required to relieve headache, sore throat and general discomfort.

Daily examinations of the patient and frequent urinalyses should be made during the febrile period. Inhalation of moist air is indicated when there is severe infection of the upper respiratory tract. Cold or hot local compresses may be applied to painful, swollen cervical lymph nodes; incision should be made only when fluctuation is obvious.

The pain of otitis media is relieved by codeine and aspirin and the local application of heat. Early myringotomy is indicated if the drum is bulging. The treatment of toxic myocarditis is identical with that described under Diphtheria (p. 419). The management of acute glomerulonephritis is discussed elsewhere (p. 1041). The secondary anemia quickly responds to administration of an adequate diet, iron and cobalt.

Penicillin is the antibiotic of choice. Daily intramuscular injections of 300,000 to 600,000 units of an aqueous suspension of procaine penicillin for ten days is ideal. One or two daily injections followed by suitable oral therapy for a week are satisfactory and more practicable.

Although penicillin does not neutralize the toxin, it rapidly eliminates the organism and inhibits the development of streptococcal antibodies such as antistreptolysin, thus reducing the incidence of complications. However, such early effective therapy probably also interferes with the development of acquired immunity (Strom, 1955).

If penicillin cannot be used, one of the tetracycline drugs is a second choice. They are effective against the septic manifestations, but do not so readily eliminate the organism or prevent a rise of the antistreptolysin titer. Sulfonamides should be given only if penicillin and the tetracyclines cannot be used.

Since antibiotic therapy is highly effective and toxic features of the disease are seldom marked, there is little, if any, need for serum therapy. However, when indicated, gamma globulin, which contains from three to five times the amount of erythrogenic antitoxin as does the average human immune serum, may be injected intramuscularly in doses of 20 to 60 cc.

**Surgical Scarlet Fever.** In this type of the disease the focus of infection is somewhere other than the throat. It may be a traumatic or operative wound or a burn. It may follow any surgical operation, but particularly those of the ear, mouth or nose; the onset is usually within two to four days. The symptoms are usually mild, and complications are infrequent. The pharynx is not involved, and hemolytic streptococci can usually be cultured from the suspected focus.

#### ERYSIPELAS

(ST. ANTHONY'S FIRE)

Erysipelas is an acute streptococcal infection of the skin and occasionally of the mucous membranes. It is characterized locally by a painful erythematous induration with sharply demarcated serpiginous borders and generally by constitutional symptoms.

**Etiology.** A number of the subgroups of group A hemolytic streptococci may be the cause of erysipelas.

**Epidemiology.** The disease exists endemically in all communities where streptococcal

infections occur. Since the introduction of the sulfonamides and antibiotics it is relatively infrequent.

**Immunity.** The newborn infant is highly susceptible. An attack of the disease confers no immunity against subsequent ones. Certain persons appear to be predisposed to the disease and have repeated attacks. In this respect erysipelas differs from scarlet fever, in which immunity to the erythrogenic toxin (rash) is conferred. Thus it would seem that antitoxic immunity is relatively ineffective in erysipelas.

**Pathology.** Streptococci are found in great numbers in and about the lymphatics of the skin near the border of the spreading infection. The surrounding area is hyperemic and edematous. Infiltration of mononuclear cells is marked, extending into the corium and subcutaneous fatty area. Suppuration is rare except in the subcutaneous region, where it may occur in infants. The regional lymph nodes are enlarged. In young infants septicemia is frequent and results in multiple metastatic purulent lesions which may include parenchymal lesions of the liver, kidneys, brain, heart and other organs.

**Clinical Manifestations.** The local lesion is often the first evidence of infection, although at times fever, malaise, irritability, vomiting, loss of appetite or other general symptoms may precede it. The portal of entry is a wound of the skin which may be trivial or may be a surgical incision, or the lesions of such conditions as eczema, impetigo, varicella and vaccinia. The sites most frequently involved are the periumbilical area (newborn), the genitals, face and extremities. When the face is involved, the infection may extend from one cheek across the nose to the other cheek (the familiar "butterfly" type). The inflamed area is red, hot and tender, and there may be vesiculation. The border is elevated and spreads in an irregular manner, avoiding areas of the skin where tension normally exists, such as bony prominences. The disease may be self-limited or may spread over a large portion of the body, fading in one area while extension occurs in another. The fading area becomes brawny and desquamates.

Erysipelas of the mucous membranes is relatively rare. It may occur as a hard, painful, swollen inflammation of the pharynx, nose, larynx or vulva. Extension into the larynx may lead to suffocation.

The temperature usually reaches a level of

104° or 105° F. It may be intermittent, but more often remains at a high level. The fever may last only a few days or may persist for one or more weeks. Occasionally it is of a low grade type; in overwhelming infections, especially in newborn infants, the temperature may be subnormal.

Leukocytosis is usually present, the white blood cell count ranging from 12,000 to 40,000 per cubic millimeter, with a preponderance of polymorphonuclear cells. Except in infants, blood cultures are usually sterile.

Relapses are common, usually beginning in areas of skin most recently infected. The course of a relapse is usually shorter and the symptoms are less severe than in the original attack.

**Diagnosis.** The fully developed case of erysipelas offers little diagnostic difficulty.

*Diffuse cellulitis*, or infection of the subcutaneous tissue, is the condition most commonly confused with erysipelas. The constitutional symptoms are usually less pronounced, and the characteristic elevated border of erysipelas is absent. Orbital cellulitis, secondary to ethmoidal sinus infection, is occasionally misdiagnosed as erysipelas.

*Dermatitis medicamentosa*, particularly that due to mercurial ointment, may be differentiated by history and by lack of fever, as may eczema of the erythrodermic type. Severe sunburn should offer little difficulty in differential diagnosis.

**Complications.** In infancy, septicemia, bronchopneumonia and peritonitis are the most important complications. Abscess formation occurs in 10 to 15 per cent of all cases. Sloughing with ulceration results most frequently in areas subject to pressure.

Suppurative lesions of the accessory nasal sinuses sometimes occur. More extensive forms of such infections may lead to thrombosis of the cavernous sinus or other dural sinuses, meningitis or brain abscess.

**Prognosis.** The general mortality was formerly 5 to 10 per cent, and in infants as high as 80 per cent. When treatment is instituted early, recovery can be expected in practically all instances, even in infants.

**Treatment.** Although the infection is relatively noncommunicable, the patient should be in strict isolation. Erysipelas responds dramatically to the systemic administration of penicillin or other antibiotics effective against the beta-hemolytic *Streptococcus* (see p. 402). Local treatment is not effective.

## DIPHTHERIA

**Definition.** Diphtheria is a specific infectious disease caused by *Corynebacterium diphtheriae*. In its classic form it is characterized by a local pseudomembranous lesion, usually on the tonsils, pharynx and adjacent tissues, from which a powerful toxin is absorbed. This toxin produces the constitutional symptoms. The location of the lesion, its extent and the degree of toxemia vary greatly.

**History.** The modern concept of the disease began with the classic clinical description by Bretonneau in 1826, who called it *diphtherite*. Diphtheria, however, was known to the Hebrews before Christ. It is not known when the disease reached America; Samuel Bard (1771) probably described an epidemic in New York City and the Colony.

Klebs in 1883 demonstrated diphtheria bacilli in the pseudomembrane, and Loeffler in 1884 identified them in pure culture. In 1888 Roux and Yersin described the toxin, and in 1894 von Behring discovered its antitoxin. Theobald Smith suggested toxin-antitoxin for active immunization, and it was widely popularized by Park and Zingler (1913). Schick introduced the intracutaneous test for determining susceptibility in 1913, and in 1922 Ramon described the preparation of formalized toxin (toxoid). The introduction of tracheotomy (1825) by Bretonneau and of intubation (1895) by O'Dwyer were also important contributions.

**Etiology.** The diphtheria bacillus is polymorphous, but characteristically is a slender, slightly curved, sometimes clubbed organism. In smears prepared from cultures the bacilli tend to group themselves in parallel (palisade) or V-shaped formations. The stained protoplasm of the organism may appear uniform in consistency or may be granular or barred. Dark-staining polar bodies at or near the ends of the organism are characteristic. Smears for diagnosis are usually stained with methylene blue, toluidine blue or Ljubinsky's stain. Characteristic bacilli may be found on smears made directly from lesions in the majority of instances, but they cannot be differentiated by this means from nonpathogenic diphtheroid bacilli. A negative smear does not rule out the presence of the organism in the lesion.

The bacillus is gram-positive, nonmotile and nonspore-forming. It is easily destroyed by heat (60° C. for ten minutes) and is susceptible to weak antiseptics. It survives in ice for several weeks. In water, milk or dried mucus it may remain viable for several weeks.

Three types of the organism, *gravis*, *mitis* and *intermediate*, may be identified by the type of colony formed on a blood-agar me-

Table 67. Death Rates for Diphtheria by Age\*; All Races, Both Sexes: Death Registration States 1920-1953

Year	Total	Under 1 Year	1-4 Years	5-14 Years

\* Rate per 100,000 population of age group.

dium containing potassium tellurite. The gravis and intermediate forms are thought to be associated with a high fatality rate and the mitis type with the milder forms of the disease. Frobisher, however, found no constant relation between the gravis form and malignant diphtheria.

The diphtheria bacillus produces a powerful toxin. Guinea pigs die when injected with doses as small as 0.02 ml. Approximately one fiftieth of this amount of toxin is used for intradermal injection to determine susceptibility of man to the disease (Schick test). If no reaction occurs at the site of injection, the person is considered immune and to have at least 1/30 unit of antitoxin per milliliter of blood serum. (Some evidence suggests that as little as 1/250 unit may neutralize the skin test.)

The toxin, a heat-coagulable protein, accounts for practically all the clinical manifestations. It is a potent tissue poison which, within a few hours after absorption, produces characteristic cellular changes, especially in the cardiac, renal and nervous tissues.

**Epidemiology.** Diphtheria occurs endemically and epidemically throughout the world, particularly in the temperate zones, and is more frequent during the winter. Though the incidence is slightly greater among females, there is no significant difference in mortality between the sexes. Negroes are said to have greater immunity than white persons.

Diphtheria has a characteristic age incidence, corresponding to the lack of humoral antitoxin. The disease is rare during the first six months of life; the incidence reaches its peak between the second and fifth years, and it declines rapidly beyond the age of ten. In the United States about 65 per cent of cases have occurred in children under five years of age. There is, however, evidence of a rising

age incidence, which may be the result of extensive active immunization among the younger age groups. Such evidence indicates the continued use of "booster injections," at least throughout the school years (see p. 141).

The morbidity and mortality from diphtheria have declined rapidly in the United States, particularly since 1920, when active immunization became widely established (Table 67).

Diphtheria is particularly apt to be spread in schools and other places where children of susceptible ages are grouped together. One or more chronic carriers may account for its persistence within a particular community. The recent discovery that, in the presence of a specific bacteriophage, certain avirulent strains can become permanently virulent adds importance to the role of the carrier.

Infection is due to contact with a person with the active disease or with a carrier of virulent organisms. Fomites and animals play an unimportant role in the transmission of the disease, as do water and milk. Chronic sinusitis and diseased tonsils and adenoids are important predisposing factors.

**Immunity.** Resistance to *C. diphtheriae* is of two types: passive and active.

*Passive immunity* may be obtained by the newborn infant transplacentally from an immune mother. It is almost absolute for the first three months of life and partial until about the sixth month. If the mother is susceptible to diphtheria, her baby is also susceptible. Passive immunity for about three weeks may be artificially obtained by subcutaneous injection of 1500 units of antitoxin.

*Active immunity* is acquired by having the disease or by receiving inoculations of one of several types of suitable antigens. Not all persons recovering from the disease become immune; hence secondary attacks are not uncommon. It is probable that the early injection of antitoxin, though curative, interferes with the patient's power to generate antibodies. Conversely, not all persons immune to diphtheria have had the classic disease. Active immunity is presumably induced by subclinical diphtheritic infections. Occasionally a susceptible person lacking demonstrable humoral immunity as reflected by a positive Schick reaction fails to contract diphtheria in spite of repeated exposures to virulent organisms. This suggests that resistance may depend upon cellular as well as humoral immunity.

**Schick test.** The minimal lethal dose

(M.L.D.) of diphtheria toxin is defined as that amount which, injected subcutaneously, causes the death of a 250-gm. guinea pig within four days. The Schick test consists in intracutaneous injection of 1/50 M.L.D. of toxin contained in 0.1 ml. of a proper diluent. If the tested person is susceptible, an area of reddish-brown discoloration appears at the site of injection within twenty-four hours. In persons who have practically no antitoxin, vesication often occurs. After five to seven days the reaction begins to fade, leaving a scaling, wrinkled area with brownish pigmentation which may last four to six weeks. If the tested person is immune, no local reaction occurs unless he is allergic to the auto-lyzed substance of the diphtheria bacillus or to other protein components of the culture medium or diluent solution. In this case a pseudoreaction manifested by a diffuse erythema with or without an urticarial wheal develops within a few minutes or hours. It usually disappears within seventy-two hours. A control test has been devised consisting of a material identical with that used for the test except that the toxin has been destroyed by heat. In some clinics the control test is omitted, and the interpretation is made at the end of the fifth day, when pseudoreactions have usually disappeared.

Four types of Schick reactions are commonly observed (Fig 114).

About 15 per cent of newborn infants have positive Schick reactions. In such instances the mother's reaction is almost always positive. The incidence of positive reactions gradually increases until the sixth month of age, when about 50 per cent are positive. At one year fully 90 per cent of nonimmunized infants have a positive reaction; after this age the incidence until recent years gradually diminished, until at seventeen years only about 15 per cent remained positive. Surveys, however, indicate that 50 to 60 per cent of adolescents and adults now have positive reactions.

**Pathology.** An exotoxin elaborated by the organisms tends to inhibit the local inflammatory response. As this response is overcome the bacteria multiply rapidly and produce more toxin, resulting in edema, hyperemia and necrosis of the epithelium. A pseudo-membrane, consisting of fibrin, leukocytes, necrotic tissue and bacteria, is formed and becomes adherent to the underlying tissue. Removal of it exposes a raw, bleeding surface. The membrane is less adherent to columnar epithelium than in the trachea, and is more

readily separated from its attachment. Pseudomembranes may be absent in early or mild forms of the disease and may be present in diseases other than diphtheria.

Pharyngeal membranes may extend to the nasopharynx into the larynx, or the lesion may be localized to the latter site. Primary tracheal diphtheria is rare, involvement of the larynx almost always being present. Since the tracheal membrane is easily detached, not being in contact with an extensive vascular bed, the toxemia may be much less than in the pharyngeal type. The tracheal membrane often becomes loose except at its point of attachment in the larynx and may cause obstruction in the lower respiratory tract. Rarely an almost perfect cast of the bronchial tree may be formed by an extensive membrane.

Lymph nodes draining the affected area, and at times more remote ones, reveal reactive hyperplasia. The malpighian corpuscles of the spleen and of the lymph nodes contain large toxic reaction centers.

In patients dying with toxic myocarditis, the heart is soft and flabby, and the chambers, especially the left ventricle, are dilated. Scattered petechiae may be present. Histologically, there are interstitial edema and multiple areas of necrosis associated with an inflammatory infiltrate consisting predominantly of polymorphonuclear leukocytes. In less severely involved areas droplets of fat may be demonstrable within the myocardial fibers.

Paralysis results from the effects of the toxin on the peripheral nerves. There is degeneration and even destruction of myelin sheaths, and the axons may be swollen. Rarely does irreparable axonal damage occur.

Cloudy swelling and occasionally focal necrosis may be present in the liver and kidneys; rarely is there acute interstitial nephritis.

Death may result from peripheral vascular collapse, respiratory obstruction, cardiac failure, respiratory paralysis or secondary bronchopneumonia.

**Clinical Manifestations.** The incubation period is from two to seven days.

**Faucial diphtheria.** The disease may be so mild that it is overlooked, or discovered only by bacteriologic examination, since only a catarrhal inflammation may occur. Infection without membrane formation is particularly likely in partially immune persons.

In the moderately severe case there may or may not be soreness of the throat, but malaise and headache are usually present. Fever is usually of the low grade type, 101° to 103° F. Inspection during the first day reveals con-

FIG. 114. Schick test and control reactions 24 to 48 hours after injections (see text for more complete description). A, Positive reaction: patient susceptible to diphtheria and not allergic to protein material in test solution. B, Positive combined reaction: patient susceptible and also allergic to protein in test solution. C, Pseudoreaction: patient immune, but allergic to protein in test solution. D, Negative reaction: patient immune and nonallergic to protein material in test solution.

gestion and slight swelling of the tonsillar and pharyngeal tissue, with slight enlargement of the cervical lymph nodes. Within twenty-four hours small yellowish-white spots appear upon the surface of the tonsils. They closely resemble those of follicular tonsillitis and are removed with difficulty. The spots coalesce and spread rapidly from the tonsillar surface to the pillars, uvula, soft palate and posterior pharyngeal wall. The membrane may extend upward into the nares and cause a bloody, serous nasal discharge. The odor is offensive, but not characteristic. Swelling of the soft tissues and cervical lymph nodes develops. Constitutional symptoms increase in severity, and the pulse becomes rapid and of less volume. The blood pressure falls, and prostration becomes pronounced. Difficulty in swallowing increases, and noisy breathing becomes evident even without laryngeal obstruction. A nasal voice or regurgitation of liquids through the nose during the act of swallowing suggests palatal paralysis. The patellar reflexes may be diminished or absent. In severe cases there is rapid reduction of erythrocytes and hemoglobin. Polymorphonuclear leukocytosis develops. The urine usually contains albumin, and often hyaline and epithelial casts.

The more malignant type of the disease is usually a combined faucial and nasopharyngeal lesion. Toxemia in this form is extreme, and the sensorium is frequently disturbed. The local infection is extensive, and there may be secondary infection, frequently with the hemolytic *Streptococcus*. Hemorrhages from the mouth and nose are common, and petechiae, resulting from capillary fragility, may appear in the skin and mucous membranes. The cervical lymph nodes may become greatly swollen and, with the firm, non-pitting edematous changes in the surrounding skin and subcutaneous tissue, create a characteristic "bullneck" appearance. The face becomes edematous and has a waxy pallor. Death usually occurs within a week from toxic myocarditis or bronchopneumonia.

**Laryngotracheal diphtheria.** In about one fourth of all cases the infection invades the larynx and trachea, the laryngeal lesion being an extension from a pharyngeal focus about three times as often as it is primary. It is more common in infants and has a high mortality rate. There is less toxemia in the primary form.

Hoarseness, a brassy cough and noisy breathing are the initial symptoms. Laryngeal obstruction is soon apparent and is progres-

sive with stridor that is both inspiratory and expiratory. Restlessness, anxiety and retractions of the episternal and subcostal regions increase; if the obstruction is not relieved, cyanosis develops, and death occurs from suffocation or cardiac failure.

Laryngoscopic examination reveals edema, congestion and the pseudomembrane.

**Nasal diphtheria.** In about 2 per cent of all cases, more often in infants, diphtheria may occur primarily in the nose, where the infection may remain localized or extend to the nasopharynx, throat and larynx. When the lesion is limited to the nose, constitutional symptoms are usually absent or slight, and the fever tends to be low. The only evidence may be a nasal discharge which characteristically is sanguineous and has a foul odor. Obstruction to breathing may be present. Nasal diphtheria, because of its chronicity, constitutes a continuous source of contagion if not discovered.

**Cutaneous diphtheria.** Cutaneous infection is not unusual in the tropics, as was observed in the armed forces during World War II in Africa and in the Pacific theatre. It is said to be common in New Guinea, where faucial diphtheria has not been reported. In a series of 1423 cases of diphtheria (Los Angeles County Hospital, 1945-50) there were six instances of cutaneous infection and ten of infection in the ear, conjunctiva, umbilicus or vagina.

The skin infection may be primary or secondary to lesions of the mucous membranes. A common form consists of a gray membrane around the swollen edge of a wound. Other lesions may be eczematous, impetiginous, pustular or bullous. Constitutional reactions range from none to a fatal toxemia. The lesions usually respond promptly to specific treatment.

**Other types of diphtheria.** Primary infection may occur in unusual regions of the body, or these areas may become secondarily infected from a diphtheritic lesion in the upper respiratory tract. The vulva, vagina, umbilical cord, conjunctivas and cutaneous wounds are some of the unusual sites. Lesions on the lips and face may also occur. Wounds, especially those resulting from tonsillectomy, are at times infected. Tonsillectomies should be performed only on children known to be Schick-negative.

**Diagnosis.** There is nothing typical about the early tonsillar lesion, except the manner and rapidity of extension of the membrane. A throat swab should be obtained for culture

and smear at the initial examination. If dependable bacteriologic facilities are not available, antitoxin should be administered immediately in each suspected case.

Bacteriologic diagnosis of diphtheria requires (see also p. 387) (1) good culture medium, (2) proper technique of taking the culture, and (3) expert interpretation of stained smears. The mediums should be fresh and moist. A drop of water of condensation at the bottom of the slant is desirable. The swab should be made from the base of the exudate or membrane. Direct smears are important only when positive and diphtheroid organisms cannot be differentiated; a negative culture does not rule out diphtheria.

In doubtful cases, particularly in patients under observation in a hospital, the following routine may prove helpful: (1) an accurate history concerning previous active immunization and Schick reaction, (2) incubation of a culture from the lesion, (3) performance of a Schick test, (4) careful, regularly repeated examination of the throat lesion, and (5) immediate therapy with penicillin. If the membrane spreads, antitoxin should be administered even if the culture is negative. A rapid method of culturing the organism consists in the use of a swab impregnated with horse serum, the surface of which is coagulated by passing the swab through a flame. Charged swabs prepared in this manner, when incubated, often show growth of *C. diphtheriae* within two to four hours.

**Differential Diagnosis. Nasal diphtheria.** This lesion may be confused with any condition responsible for a persistent bloody nasal discharge. Ulcers produced by constant picking of the nose, foreign body and congenital syphilis are the more common conditions that require consideration.

**Faucial diphtheria.** Faucial diphtheria is most likely to be confused with follicular tonsillitis, in which the temperature is usually high, swallowing is painful, and the follicular exudates, though they may coalesce, do not usually extend beyond the surface of the tonsils. In early syphilis primary or secondary ulcerative lesions may resemble those of diphtheria. They are more frequent in adults, and the specific serologic reaction is positive. Severe pharyngeal reactions to herpes virus occasionally suggest diphtheria; but characteristic herpetic lesions of the tongue, cheeks, lips and gums are usually present or soon develop. In severe or septic cases of scarlet fever, tissue swelling, ulceration and heavy mucoid exudate over the tonsil, soft palate

and posterior pharyngeal wall may occur. The throat lesion of *infectious mononucleosis* may be confusing. *Thrush*, usually encountered during infancy, occurs in other areas of the oral cavity as a rule, and the exudates are whiter than that of diphtheria and characteristically arranged as small linear (filaments) membranes. The membranes which characteristically form in *post-tonsillectomy wounds* have been mistaken for diphtheria. In certain *blood dyscrasias*, such as agranulocytosis and leukemia, necrotic lesions occur in the throat which may resemble those of diphtheria.

**Laryngeal diphtheria** (see also p. 778). This lesion is most frequently confused with *acute laryngitis* and *laryngotracheobronchitis*. Clinical differentiation of these conditions is often not possible. Direct laryngoscopic examination offers the best assistance both for direct visualization and for obtaining material for culture. *Spasmodic croup* produces an intermittent rather than progressive stridor. It often occurs in a child known to have had previous attacks and frequently responds to ipecac, sedatives and a moist atmosphere. *Bronchopneumonia* in infants may be characterized by dyspnea, hoarseness and stridor with retraction; this is especially true of acute bronchiolitis (p. 795). The stridor of *bronchial asthma* is principally expiratory and usually responds to a test dose of epinephrine. Retropharyngeal or peritonsillar abscess, mediastinal tumor, edema of the glottis, papilloma of the larynx, and tetany are other conditions which at times must be considered. The patient with an acute stridor should be examined with the direct laryngoscope and a culture taken from the upper trachea.

**Complications.** Complications vary in epidemics and with the promptness with which specific antitoxin therapy is instituted.

**Respiratory complications.** *Bronchopneumonia* is common, particularly in infants and especially in conjunction with the laryngeal form of diphtheria. It is usually caused by other organisms than *C. diphtheriae*. It occurs in over half of the fatal cases.

*Atelectasis* is associated particularly with laryngeal and tracheal lesions.

**Circulatory complications.** Circulatory failure is one of the most important complications. Early circulatory failure is the result of toxemia. Late circulatory failure occurs during apparent convalescence and is due to changes in the peripheral vasomotor mechanism. Cardiac failure is due to acute toxic myocarditis with or without superimposed damage to the intrinsic conduction system. It may occur at

any time during the disease, but most commonly between the fifth and twelfth days. The symptoms are fatigue, dyspnea and a weak, rapid pulse. At times the pulse rate is very slow, in some, but not all, instances caused by heart block. The heart sounds, particularly the first, become feeble, and often there is an associated gallop rhythm. Enlargement of the liver, epigastric pain, vomiting, cardiac dilatation, pallor and diminished blood pressure are characteristic findings. The electrocardiogram reveals an increased P-R interval and inversion of the T wave in the first and second leads.

**Renal complications.** *Albuminuria* is common during the febrile stage of the disease. It is due to toxic degenerative changes in the renal epithelium. In the more severe cases there is usually a mild generalized edema. The urine is diminished in volume and contains leukocytes, epithelial cells and hyaline casts, but seldom erythrocytes. Clinical evidence of *nephritis* exists in about 10 to 15 per cent of all cases; postmortem studies reveal renal changes in the majority of fatal cases.

**Paralysis.** Paralysis occurs in 10 to 15 per cent of all cases as the result of a toxic peripheral neuritis which is painless, usually persists for several days or weeks and may involve any muscle or group of muscles. The time of onset and the extent of the paralysis depend upon the severity of the disease and the time when antitoxin is given.

**Palatal paralysis** is the most frequent and usually the first type to appear. This usually appears during the first or second week of the disease. The patient cannot elevate the palate, the voice becomes nasal, and regurgitation of fluids through the nares occurs upon attempts at swallowing. Palatal paralysis occasionally is recurrent.

**Paralysis of the ocular muscles** is the second most frequent type, usually involving the muscles of accommodation. Inability to read may be the first evidence. Strabismus, dilatation of the pupils and ptosis of the eyelid may occur. Ocular palsy occurs usually during the third week or later.

Progressive **general paralysis**, involving the face, neck, trunk and extremities, may follow the palatal or ocular type. It usually occurs after the fourth week of the disease. Inability to raise the head is characteristic. The deep tendon reflexes, especially the patellars, become diminished or absent, though at first they may be increased. The superficial reflexes are frequently obtainable. The Guillain-

Barré syndrome has been observed in association with diphtheria.

**Paralysis of the phrenic nerve** occurs in the severest cases. Cough, dyspnea, thoracic breathing and cyanosis are present. The forced respiratory efforts induced by the patient's fear of suffocation are impressive. Respiratory paralysis usually occurs during the fourth to the eighth week of illness and may be fatal. It is often associated with pneumonia or myocarditis.

Paralysis of the pharyngeal and laryngeal muscles usually occurs during the third week and often results in accumulation of secretions and liquids in the lower respiratory tract. Aphonia obviously results.

Except for the unusual occurrence of monoplegia or hemiplegia resulting from thrombosis of a cerebral artery, there is complete recovery from diphtheritic paralysis. Though marked involvement usually lasts but one or two weeks, complete recovery may not occur for several months.

**Unusual complications** include pleurisy, arthritis, septicemia, empyema, thrombosis and embolism. Chronic laryngeal stenosis may follow tracheotomy, particularly when the incision is made too near the larynx (p. 780).

Occasionally there are relapses and recurrences of diphtheria, the latter usually being less severe than the original attack.

**Prognosis.** The fatality rate from diphtheria is 3 to 5 per cent. In general the prognosis depends on the stage of the disease when an adequate and properly administered amount of antitoxin is injected. When specific treatment is carried out on the first day of the disease, the mortality rate is about 0.3 per cent; on the third day, 4 per cent; on the fourth day, 12 per cent; and on subsequent days, 25 per cent. In young infants the fatality rate is higher, owing to the frequency of laryngeal involvement and of bronchopneumonia. Septic symptoms, cardiac involvement and hemorrhagic manifestations are unfavorable complications. The virulence of the organism and the location and extent of the membrane are important prognostic factors. Secondary infections obviously may influence the outcome.

**Prevention.** Immediate contacts should be subjected to Schick tests, nose and throat cultures and daily inspection. Penicillin should be given intramuscularly or orally.

Previously immunized contacts should receive a booster injection of fluid toxoid. Those with negative Schick tests and positive cultures should be treated as carriers. Those

with positive Schick tests and positive cultures should be treated as active cases with antitoxin (2000 units) and with either penicillin or erythromycin. Contacts not previously immunized, but showing positive Schick reactions, should later be actively immunized with toxoid.

When the foregoing regimen is not possible, it may be safer to provide passive immunity for the immediate contacts with a subcutaneous injection of 2000 units of antitoxin after proper testing for sensitivity. They should also receive penicillin.

Isolation of the patient should be maintained until two negative cultures on consecutive days have been obtained from the nose and throat. The first culture should not be taken until one week after the onset of the disease. If the second culture is positive, five days should elapse before another culture is taken. The child should not return to school for at least three weeks after the onset of illness.

**Active immunization** (see p. 139). The most important preventive measure is active immunization during infancy. Four types of antigenic substances have been successfully used for this purpose: toxin-antitoxin, toxoid, alum-precipitated toxoid and floccules.

**TOXIN-ANTITOXIN.** Although toxin-antitoxin is a good antigen, it has the following disadvantages: It is difficult to prepare; the mixture has a tendency to dissociate under certain conditions; and there is the possibility of sensitization to horse serum.

**TOXOID.** Ramon showed that diphtheria toxin is rendered nontoxic, but remains highly antigenic, when treated with a small amount of formalin. This product, known as anatoxin or toxoid, is widely used for active protection. It is more stable, easier to prepare, and is probably more effective than toxin-antitoxin.

**ALUM-PRECIPIATED TOXOID.** The precipitated toxoid is absorbed more slowly from the site of injection, thereby resulting in prolongation of the antigenic stimulus.

**FLOCCULES.** Floccules consist of the precipitate formed by a mixture of toxoid and antitoxin. It is widely used in England.

The practice of combining diphtheria and tetanus toxoids in the precipitated form has become common, and a "triple vaccine" which includes pertussis vaccine is also frequently used (see p. 139).

Early administration of antitoxin may interfere with production of immunity during an attack of diphtheria, a factor probably accounting for many of the second attacks. Hence it is advisable to Schick test the patient convalescing from the disease after the anti-

toxin administered therapeutically has been eliminated (six to eight weeks). If the reaction is positive, he should receive active immunization.

**Management of the carrier.** Diphtheria is one of the classic "carrier diseases." In about three fourths of the cases of diphtheria the organisms disappear from the upper respiratory tract within three weeks after the acute phase. In the remaining fourth, organisms may be retained for months. This type of carrier, known as the convalescent carrier, and the contact carrier, who has been closely associated with an active case, are epidemiologically important because they can be assumed to harbor virulent organisms. Only about 10 per cent of the carriers discovered by surveys harbor virulent organisms.

The incidence of convalescent carriers is decreased when treatment during the acute stage includes antitoxin and either penicillin or erythromycin.

The nonconvalescent carrier should be treated with penicillin or erythromycin. In persistent carriers foci of infection in tonsils, adenoids and sinuses should be eliminated. If the carrier is Schick positive, the operation should be deferred until he has been actively immunized. Penicillin should be given immediately before and after the operation.

Carriers should be isolated until virulent organisms are no longer demonstrated by culture.

**Treatment. General care.** The patient should be kept absolutely quiet in bed for at least two weeks. If the membrane extends beyond the surface of the tonsils or if antitoxin was not given until late in the course of the disease, this period should be extended. Daily physical examinations are essential. If there is the slightest doubt about the status of the circulatory system, an electrocardiographic tracing should be obtained. Intravenous injections of 10 per cent glucose solution (about 1 gm. per kilogram per day) are indicated to counteract the tendency to hypoglycemia associated with toxemia. A fluid or soft diet ample in vitamin content should be given. Saline throat irrigations may prove helpful, and an ice collar is comforting when the cervical lymph nodes are swollen. Codeine and aspirin may relieve suffering from sore throat or headache.

*Penicillin should be administered in addition to antitoxin, not as a substitute.*

**Specific treatment.** This consists in the early injection of an adequate amount of antitoxin. From 10,000 to 20,000 units of

antitoxin may be injected intramuscularly in cases of average severity. In the toxic, the complicated or the laryngeal case 20,000 to 40,000 units should be administered, one half intramuscularly and one half intravenously. If improvement in the local or general condition of the patient is not apparent within twenty-four hours, more antitoxin may be administered. Injected antitoxin neutralizes only the toxin free in the circulatory system and that which will be absorbed later; it has no effect upon that which is already bound by the body cells.

**SENSITIVITY TEST.** Preliminary testing of the patient for sensitivity to horse serum should always be made before antitoxin is administered. This is done by injecting 0.05 cc. of a 1:20 dilution of horse serum intracutaneously, or a similar amount of the antitoxin.

**DESENSITIZATION.** In the event of a local reaction (a wheal with an area of erythema appearing within ten to thirty minutes) or general reaction to the preliminary test, careful desensitization of the patient should be carried out.

Serial injections of diluted antitoxin as indicated below may be made at intervals of fifteen minutes, provided no reaction occurs. If a reaction occurs after an injection, one should wait an hour and then repeat the last dose which failed to cause a reaction.

1. 0.05 cc. of a 1:20 dilution of antitoxin, subcutaneously
2. 0.05 cc. of a 1:10 dilution of antitoxin, subcutaneously
3. 0.1 cc. of undiluted antitoxin, subcutaneously
4. 0.2 cc. of undiluted antitoxin, subcutaneously
5. 0.5 cc. of undiluted antitoxin, intramuscularly
6. 0.1 cc. of undiluted antitoxin, intravenously
7. The remainder of the therapeutic dose is slowly injected intravenously.

In a person known to be allergic to horse emanations extreme care should be used, or bovine antitoxin should be substituted. A syringe containing epinephrine chloride solution should always be available when antitoxin is being injected.

**Complications.** The management of complications, especially circulatory failure and paralysis involving the mechanisms of swallowing and respiration, is often difficult. The therapeutic principles for the management of diphtheritic myocarditis are the same as those in other types of acute myocarditis. Absolute rest is essential, and intravenous therapy is often necessary. Though once considered to

be contraindicated, digitalis is now thought to be of value in diphtheritic myocarditis and should be given if possible before there is evidence of decompensation. Oxygen, sedatives, a salt-poor diet and diuretics are indicated in cardiac insufficiency.

For shock and peripheral circulatory collapse, measures, such as the use of plasma, blood and ephedrine, designed to raise the blood pressure and to restore blood volume should be instituted. Cortisone should be used as recommended for circulatory failure in meningococcemia (p. 428).

Paralyses or weakness of the extremities requires rest, splinting and appropriate physical therapy. A polyethylene tube is useful for gastric feeding when muscles concerned with swallowing are involved. The respirator should be used early for respiratory paralysis, and maintenance of an adequate airway should be ensured. The emotional problems of both child and parent must be taken into account.

**Laryngeal diphtheria.** In addition to the general and specific measures, relief of obstruction to breathing is necessary. This is accomplished by aspiration, intubation or tracheotomy. When, and which method to use are often difficult decisions. If the patient can rest and sleep quietly in a moistened atmosphere, intervention may not be required. However, increasing restlessness, anxiety and increasing retractions of the suprasternal and substernal structures indicate increasing obstruction which needs relief. Cyanosis indicates that relief is urgent. Sedatives should be withheld during this period of observation, for they may conceal important symptoms.

In certain instances aspiration of the membrane by direct laryngoscopy may provide an adequate airway, but has the disadvantage that more edema and further obstruction may result from the manipulation.

Intubation, now seldom used, has obvious technical difficulties, and the intubated patient requires constant and skillful care.

Tracheotomy is now regarded as the most effective and safest method. It can be performed under local anesthesia, with slight risk of pneumomediastinum if no dissecting is done during the procedure (p. 780). One of its greatest advantages is the ease with which suction may be carried out. The tube can usually be removed after seven to ten days. During this period antibiotic therapy should be maintained.

## PERTUSSIS

## (WHOOPIING COUGH)

**Definition.** Pertussis is an acute infection of the respiratory tract caused by *Hemophilus pertussis*. In its typical form the disease is characterized by a series of repeated spasmodic coughs ending in a forced inspiration (the whoop) and at times followed by vomiting. In mild cases neither the whoop nor the vomiting may be present.

**History.** De Baillou in 1578 wrote the first classic description of the disease. Bordet and Gengou (1906) described a small, coccoid bacillus, which they found in the sputum of active cases. Since then Shipley, Holt and others have experimentally reproduced the disease in the chimpanzee, and the MacDonalds, in susceptible children. Goodpasture and Gallavan, by an ingenious method of inoculating the chorio-allantoic membrane of the developing chick embryo, produced a pathologic lesion of the bronchial epithelium which is essentially that found in the human disease. Leslie and Gardner (1931) demonstrated the differences between the antigenic properties of the smooth (phase I) and the rough (phase IV) types of organism.

**Etiology.** *Hemophilus pertussis* is regularly present in the upper respiratory tract

FIG. 115. Reported incidence of pertussis in United States (1931-50). (From Vital Statistics-Special Reports, Vol. 37, June 15, 1953.)

during the early stage of the disease. It is seldom found in persons without symptoms, but is occasionally recovered from immediate contacts of an active case.

**Epidemiology.** Worldwide in distribution, pertussis exists in most of the thickly populated communities, where it prevails epidemically at intervals of two to four years. Although it occurs throughout the year, the peak incidence occurs in May in the southern states, and during January and February in the northern ones. The communicability rate is high, approaching that of measles and of chickenpox. In family exposures it is between 75 and 90 per cent.

Pertussis may occur at any age. The youngest patient observed by the author was two weeks of age, the oldest seventy-seven years, but about 50 per cent of all cases occur under four years of age. Since 1935 there has been a definite decrease in the number of reported cases (Fig. 115). The incidence varies in different regions of the country and is higher in the female, especially above the age of ten years.

**Immunity.** Susceptibility to the disease is great. In contrast to the temporary immunity to measles and diphtheria, the newborn infant is usually highly susceptible to pertussis. Proved second attacks are rare, though they are often suspected clinically. Humoral antibodies, as demonstrated by the agglutinin titer and by complement fixation and mouse protective tests, appear during convalescence from an attack and after active immunization with a suitable antigen. The organism appar-

ently possesses more antigens in common with *H. bronchisepticus* than it does with *Hemophilus parapertussis*. Bacterial immunity to these three organisms appears to be more specific than does that to the toxin.

**Pathology.** The lesions are located principally in the bronchi and bronchioles, although changes are present in the trachea, larynx and in the nasopharyngeal mucosa. Numerous bacilli are entangled within the cilia of the columnar ciliated epithelium, which may be covered by a mucopurulent exudate. The essential lesion consists in necrosis of the basilar and midzonal epithelium, with a focal infiltrate of neutrophils and macrophages. An infiltrate of lymphocytes and, to a smaller extent, of neutrophils is present in the walls of the respiratory passages and extends outward into the interalveolar septums to produce a peribronchial interstitial pneumonitis. Plugs of mucus are occasionally present in the small bronchi, with resultant obstructive emphysema and atelectasis. Little exudate is found in the alveoli unless secondary infection has occurred. Bronchiectasis may result from the pulmonary lesions. Small foci of hemorrhage may be found in the brain, but whether a true encephalitis occurs is not established.

**Clinical Manifestations.** The incubation period varies from seven to fourteen days. The course of the typical disease is about six weeks, representing three stages: catarrhal, spasmodic and convalescent, each lasting approximately two weeks.

The clinical course of pertussis is extremely variable. The disease may exist in an extraordinarily mild form and may occur without vomiting, whoop or even spasmodic coughing. In two proved cases in nonimmunized persons the duration of cough was one week, and in a previously immunized patient only four days.

**Catarrhal period.** The onset is usually insidious with a mild cough, often nocturnal. During the next ten days the cough becomes progressively intense, spasmodic and diurnal. Coryza, sneezing and anorexia are frequently present, and hoarseness occasionally. In rare instances the disease resembles acute obstructive laryngitis.

**Spasmodic period.** Near the end of the second week the cough becomes aggravated. In the typical severe paroxysm a series of explosive efforts occurs, and the patient appears to strangle; the face becomes red and in some instances cyanotic; it temporarily appears swollen, and anxiety is apparent. The

paroxysm ends with a sudden forceful inspiratory crow or whoop, often followed by vomiting or by the coughing up or swallowing of large amounts of thick, tenacious, mucoid sputum. Sweating, congestion of the neck and scalp veins, mental confusion, convulsions and exhaustion may follow the spells of violent coughing. Infants may become so cyanotic that artificial respiration and oxygen inhalation are necessary. In small infants choking spells may replace the characteristic whoop. Activity, excitement, sudden changes in temperature or inhalation of irritating fumes tend to provoke paroxysms. Epistaxis often occurs, and subconjunctival hemorrhages and puffiness of the lower eyelids are common in severe cases.

**Convalescent period.** About the fourth week the number and severity of the paroxysms decrease, vomiting becomes less frequent, and the appetite returns. The hilar and basilar rhonchi disappear. An intercurrent infection, such as the common cold, may cause return of the major symptoms even to the point of resembling a new attack.

**Diagnosis.** Typical severe pertussis is readily recognized during the paroxysmal

FIG. 116. Small bronchus from a case of human pertussis, showing necrosis, desquamation and inflammation in and beneath epithelium.  $\times 120$ . (Gallavan and Goodpasture: *Am. J. Path.*, Vol. 13.)

stage. In the early stage and in the atypical forms, however, it may be difficult to diagnose. The disease may be suspected when a progressive nocturnal cough becomes diurnal and continues in a spasmodic form, and when the physical examination reveals no obvious explanation of its cause. Since a history of exposure is often not elicited, it may be necessary to defer diagnosis until the cough becomes more characteristic. In such an instance the patient should be isolated and a culture taken.

The characteristic lymphocytosis appears during the late catarrhal or early paroxysmal stage. Average leukocyte counts range from 15,000 to 45,000 cells per cubic millimeter of blood, with a progressive increase in the number of lymphocytes; infrequently the count may be as high as 250,000. On occasion the lymphocytes may appear late, or the percentage of them may be equivocal.

The causative organism may be isolated from the upper respiratory tract by the cough-plate culture method or, preferably, by the nasopharyngeal swab method (see p. 387). Bacteriologic diagnosis is particularly helpful in the catarrhal stage and in the atypical case. A negative culture does not eliminate the possibility of pertussis.

Serologic tests for the presence of humoral antibodies include determination of the agglutinating titer, the complement-binding power or the mouse protective value. Since these all appear at the height or during the convalescent stage of the disease, they are of no value in early diagnosis.

**Differential Diagnosis.** A spasmodic cough similar to that of pertussis may be observed in tracheobronchitis, bronchiolitis and interstitial pneumonitis caused by a variety of agents. On occasion, epidemics of respiratory infection in infants and small children have so closely resembled pertussis clinically that it could be excluded as a diagnosis only by failure to isolate *H. pertussis* and by absence of the usual changes in the white blood cells.

Other clinical conditions which may resemble pertussis include sinusitis or adenoiditis with postnasal discharge, allergic rhinitis and bronchitis, endobronchial tuberculosis, foreign bodies in the larynx or trachea, the combination of tetany and upper respiratory infection and the respiratory infection associated with cystic fibrosis of the pancreas.

*Parapertussis*, caused by *Hemophilus parapertussis*, resembles mild pertussis so closely that it can be differentiated only by culture.

An attack of one disease does not protect against the other.

**Complications. Respiratory tract.** The most frequent complications are in the respiratory tract. *Otitis media* is common, especially in infants, and is usually caused by secondary invading organisms. *Bronchitis* is so common that it may really be considered a part of the disease. *Bronchopneumonia* is by far the most important complication and is usually interstitial in type. Atelectasis is common, resulting from blocking of a bronchus with mucus. Vesicular or interstitial emphysema occurs in practically all severe cases. Air may reach the cellular tissues of the mediastinum and extend into the soft tissues of the neck. Cases in which there is widespread subcutaneous emphysema are often fatal. Pneumothorax and empyema are infrequent complications. *Bronchiectasis* is more frequent than is generally recognized. A pre-existing *primary tuberculous* infection may be disseminated. *Persistent pneumonia*, *atelectasis* or *pulmonary fibrosis* are not uncommon sequels. Cardiac dilatation involving chiefly the right side of the heart is most commonly associated with a diffuse pneumonic lesion.

**Digestive tract.** Severe and prolonged vomiting may result in emaciation. Prolapse of the rectum and hernia may be secondary to straining. Diarrhea and abdominal distention occur occasionally and are difficult to manage. Ulceration of the frenum of the tongue may result from biting the tongue during the violent coughing spells; stomatitis may develop.

**Nervous system.** Convulsions are relatively common in infants. Tetany may occur when there is coexisting rickets and occasionally when there is alkalosis produced by loss of hydrochloric acid from excessive vomiting. Intracranial hemorrhages occur, but probably are infrequent as a cause of convulsions. Cerebral congestion and edema are common postmortem findings. Neurologic complications of pertussis include epilepsy, mental retardation, personality changes, spastic paralysis, myelitis, temporary or permanent visual disturbances, hemiplegia, monoplegia and aphasia. If caused by edema or congestion, they are temporary; if by hemorrhage or encephalitis, they may be permanent.

**Hemorrhages.** Hemorrhage is usually mechanical in origin, and occurs most often as epistaxis, hemoptysis and subconjunctival extravasations. The most serious type is intracranial.

**Prognosis.** From 1920 to 1953 the mortality rate from pertussis fell from 12.5 to 0.2 per 100,000 population (Table 68). Although this decrease began before the introduction of effective active immunization and antibiotic therapy, there is little doubt that these factors now play important roles.

Pertussis is conspicuous in that its mortality rate is higher among females than males. Pulmonary and cerebral sequels may constitute serious handicaps.

**Prevention.** (See also p. 138.) The infant should be carefully protected from exposure, but, when exposed, should receive passive immunization. This may be accomplished by the intramuscular injection of 2.5 cc. of gamma globulin prepared from hyperimmune human serums (Hypertussis). Prophylactic doses of one of the broad-spectrum antibiotics may also be given.

The exposed subject should be isolated for two weeks, and active immunization should be started.

During the active phase the child should be isolated for four to six weeks to protect susceptibles and to protect him from possible secondary infections responsible for many of the serious complications.

Active immunization of all infants should be started by the third month of age or earlier. This can be accomplished by the intramuscular injection of a triple vaccine (D.P.T.) (see p. 141). Because *H. pertussis* has certain allergic attributes, and encephalopathy has occasionally followed injection of the vaccine, care should be observed in immunizing infants subject to seizures. In such instances small doses of vaccine should be given.

**Treatment.** Good nursing care is essential, especially of the seriously ill infant. When vomiting is frequent, feedings should be given at shorter than usual intervals and should be reduced in quantity. Sudden changes in temperature should be avoided.

Patients with convulsions or persistent dyspnea should be placed in an oxygen tent, even though acyanotic. Strangling from excess mucus may be relieved by gentle suction and by placing the infant on his abdomen with the head lowered to facilitate drainage.

On occasion, sedation with phenobarbital may be indicated, but excessive sedation should be avoided. When convulsions occur, phenobarbital should be given intramuscularly (see p. 1122), and oxygen should be administered. Magnesium sulfate in doses of 0.05 ml. of a 50 per cent solution per pound

of body weight (0.1 ml. per kilogram) may be injected intramuscularly for its sedative effect, but not more often than twice a day.

Hyperimmune human serum (20 to 40 ml.), administered intravenously, or hyperimmune gamma globulin (5 to 10 ml.), injected intramuscularly, may be of benefit during the early stage of the disease. Immune rabbit serum (15 to 30 ml.) may also be used if the child is not sensitive to it.

The administration of pertussis vaccine or other antigens during the catarrhal period to a child previously immunized may be of limited value.

The tetracyclines and chloramphenicol are about equally effective against *H. pertussis* in doses of 25 mg. per pound of body weight per day (50 mg. per kilogram) divided into three or four doses. Chloramphenicol is not recommended for routine use because of its potential toxic effect on the bone marrow.

## PARAPERTUSSIS

**Definition.** Parapertussis is an acute infection of the respiratory tract caused by *Hemophilus parapertussis*. The disease resembles mild pertussis, from which it can be distinguished only by bacteriologic methods.

**History.** Eldering and Kendrick, and Bradford and Slavin, independently isolated the causative organism in 1937 from patients clinically suspected of having pertussis. The organism was isolated in 1933 in Copenhagen, though its clinical relationship was not recognized at the time.

**Etiology.** *Hemophilus parapertussis* is a small nonmotile, gram-negative coccobacillus, morphologically indistinguishable from *Hemophilus pertussis*. It has common antigenic fractions with both *H. pertussis* and *Brucella bronchiseptica*, but is identical with neither. *Hemophilus parapertussis* is virulent for mice, producing pulmonary lesions after intranasal inoculation that resemble those of experimental murine pertussis. A similar, though less potent, toxin is produced.

Specific humoral antibodies develop during the course of the disease, and may be demonstrable for at least three years. Second attacks have not been reported. An attack of either pertussis or parapertussis affords no immunity against the other disease. Active immunization against pertussis gives no protection against parapertussis.

**Incidence.** Bacteriologic and serologic evidence indicates that the disease is a common one, which is usually overlooked clinically. From a random sample of routine hospital admissions in Rochester (1954) 7 per cent of the children had agglutinative titers of 1:320 or higher, compared to 34 per cent against *H. pertussis*. The disease has been reported from widely separated areas, the greatest outbreak being reported by Lautrop, Copenhagen, 1954.

**Clinical Manifestations.** The incubation period is not definitely known, but is probably six to fifteen days. The onset is similar to that of pertussis, though it may be more abrupt. The cough is less severe, but is spasmodic and is sometimes followed by a whoop and less often by vomiting. The entire course of the disease is one to three weeks. The infection sometimes resembles tracheitis.

Complications are rare, though otitis media and bronchitis have been observed. Two deaths have been reported, in which the organism was isolated at autopsy.

**Treatment.** Active cases should be isolated. Therapy is usually only symptomatic.

Experimentally, polymyxin B, Terramycin and chloramphenicol are effective, though treatment with them is rarely indicated because of the usually mild course of the disease.

## MENINGITIS

For Meningitis in the Newborn Infant, Tuberculous Meningitis, Lymphocytic Choriomeningitis and Cryptococcosis, see pages 344, 469, 550 and 564.

## PURULENT MENINGITIS

Generalized meningeal disturbances are caused by a variety of pathogenic agents. Nonsuppurative meningeal reactions include meningismus, serous or aseptic, including the meningitides produced by certain viruses, and syphilitic and tuberculous meningitis. Suppurative meningitis is characterized by a purulent exudate and is caused by the Meningococcus, Pneumococcus, Streptococcus, *Hemophilus influenzae*, Staphylococcus, colon bacillus and other pyogenic organisms. In early infancy purulent meningitis is frequently caused by some member of the colon group of organisms. The typhoid bacillus and various types of the Salmonella group may cause meningitis in infancy and childhood, and nonhemolytic strains of streptococci and of staphylococci are occasionally encountered. Less frequently, organisms closely related to *Listerella monocytogenes* have been isolated from meningeal infections in human beings, as have the Friedländer bacillus, *Pseudomonas pyocyanea*, *Aerobacter aerogenes*, *Lactobacillus lactis*, the Gonococcus and others. The clinical patterns of the various purulent meningitides are usually so uniform that the etiology can be established only by bacteriologic methods.

**Treatment.** As a result of studies by Alexander and others, a better understanding of the principles concerned in the selection and use of the antimicrobial agents has been established. Intrathecal therapy, except with penicillin and streptomycin in special but infrequent circumstances, has been abandoned, as has also the use of specific antisera, except for the infrequent use of *H. influenzae* antiserum.

The decrease in mortality from purulent meningitis has been attended with a significant increase in permanent and serious neurologic and mental sequels. The reduction of them is one of the problems of the moment. Best results can be expected when the causative agent is identified at the earliest possible moment so that an appropriate selection can be made of the antibiotic agents to be used. The principal reasons for the use of more than one chemotherapeutic agent are (1) to prevent or delay emergence of resistant variants, (2) to obtain a greater and more rapid bacteriostatic or bactericidal effect, and (3) to minimize the toxic effects of the agents.

Subdural collections of fluid in infants and small children whose clinical response to therapy is not satisfactory are relatively frequent. The exact significance of this complication is not defined, but it is the policy in many clinics to perform a subdural tap when the clinical course is not considered satisfactory. See page 1087 for therapy of subdural effusion.

The adjunct therapeutic role of adrenal cortical extract and of cortisone in the shock syndrome of meningococcal infection has re-emphasized the importance of recognizing the metabolic problems as well as the infectious one (see p. 428).

Whenever meningitis is suspected, a lumbar puncture should be performed immediately. The appearance of the fluid should be noted, a cell count made and a stained smear prepared from the sediment of a centrifuged sample. When examination of the smear suggests the Meningococcus, *H. influenzae* or the Pneumococcus, a portion of the sediment is mixed with the appropriate antiserum for the detection of capsular swelling (quellung test). The results of the gram stain usually suggest the appropriate media for culture, but it is well to inoculate the following: a rabbit blood agar plate, an Endo-agar plate, and a tube of thioglycolate broth, to be incubated at 37° C., normal atmosphere. In addition, an inoculated chocolate agar plate is incubated at 37° in a jar containing 10

per cent carbon dioxide. The remainder of the fluid is incubated at 37° C. One tube of cerebrospinal fluid should be used for chemical analysis for sugar, chlorides and protein. If available, a third tube is saved for viral studies or for future reference.

In the majority of instances proper antibiotic therapy can be instituted after the preliminary examination. When no organism is found in a purulent fluid, a combination of agents, for example penicillin, sulfadiazine and chloramphenicol, is prescribed. Subsequent changes may depend upon isolation of an organism, determination of its susceptibility in vitro and/or the clinical response to therapy.

#### MENINGOCOCCAL MENINGITIS AND MENINGOCOCCEMIA

(CEREBROSPINAL FEVER, EPIDEMIC CEREBROSPINAL MENINGITIS, SPOTTED FEVER)

**Etiology.** The Meningococcus (*Neisseria intracellularis*), first described by Weichselbaum (1887), is a gram-negative, biscuit-shaped diplococcus which in the body may be found extracellularly or intracellularly. It may be responsible for infection of the upper respiratory tract, septicemia, meningitis and other metastatic lesions. Any one or all three types of infection may occur in the same subject. The three immunologic types of the organism are as follows:

*Group I* includes the old types I and III, the strains of which cross-agglutinate one another and have a common polysaccharide (Scherp and Rake). Group I strains were the most prevalent ones in recent epidemics.

*Group II* includes most of the remaining strains, many of which are serologically nonhomogeneous. Group II strains are most often encountered in non-epidemic cases.

*Group IIa* includes a number of strains formerly included in group II (Branham).

Strains belonging to groups I and IIa are encapsulated and are definitely antigenic, exhibiting capsular swelling in the presence of group-specific antisera. Group II strains are less antigenic and do not show capsular swelling with antiserum. A few strains, chiefly nasopharyngeal, do not react serologically with any of the group antisera and are included in a "polyvalent" group. Certain toxic properties of the organism are related to an endotoxin (perhaps a nucleoprotein) which may be obtained from either living or dead organisms. Group-specific exotoxins have been described, but not proved.

FIG. 117. Purpuric eruption in meningococcal meningitis in a boy  $6\frac{1}{2}$  years of age.

**Epidemiology.** The disease is endemic throughout the world; epidemics occur infrequently. Since 1916 four distinct epidemics have occurred in the United States, with their peaks in 1917, 1929, 1936 and 1943.

Both endemic and epidemic infections occur most often in late winter and early spring months. Even in the civilian population, males are infected more often than females. About 45 per cent of all cases occur in children under fifteen years of age, about 25 per cent in those under five years, and about 15 per cent in infants under one year. The case fatality rates are highest in infants and in adults over fifty years of age.

About 3 per cent of the population are carriers during interepidemic periods, and the rate may increase to 70 to 80 per cent during an epidemic. Upper respiratory infections may be caused by the *Meningococcus*, and it may be that recovery from such an infection confers immunity against subsequent, more serious infections such as meningitis.

**Immunity.** One attack of the disease usually confers permanent immunity, but relapses and recurrences do occur. Probably the bactericidal power of the blood determines whether the organisms gain contact with the meninges. This mechanism of immunity, which would support the hematogenous theory of invasion, would also explain the low incidence of the disease during the first few weeks or months of life, when the infant may have protection from placentally transferred humoral antibodies.

**Pathology.** The mechanism of infection appears to be that of a bacteremia originating from a focus in the nasopharynx, the central nervous system being infected as a metastatic focus. In the blood the organisms multiply and elaborate toxin which aids in their dissemination and localization. Petechial and purpuric areas are characteristic of meningo-

coccal septicemia and occur in the skin and in the mucous and serous membranes. Hemorrhagic and purulent metastatic lesions occur in the peritoneum, pericardium, pleura, joints, eyes and epididymis. Vegetative endocarditis may also occur.

The lesion of the central nervous system is a purulent inflammation of the arachnoid and pia mater, usually heaviest over the parietal and occipital lobes and over the cerebellum. The infection may extend to the ventricles and may obstruct the various openings, resulting in obstructive hydrocephalus. The intracranial portions of various cranial nerves, particularly the optic, facial and auditory, may be involved. Throughout the brain perivascular foci of leukocytes, round cells and red blood cells may be found, as well as hemorrhagic and necrotic areas. This aspect of the infection is often overlooked.

When there is an extensive purpuric eruption and death occurs suddenly in the initial stage, there is often a massive hemorrhage into the adrenal glands (the Waterhouse-Friderichsen syndrome, p. 1185).

**Clinical Manifestations.** Several clinical types of meningococcal infection are recognized, the most important being the meningitic and the septicemic forms.

**Meningitic form.** Meningitis is the characteristic form of the disease. The onset is abrupt with general malaise, headache and irritability. Repeated and often projectile vomiting and prostration occur. Chills and convulsions, particularly in infants, are frequent. The temperature is high, the pulse is fast, and the respirations may be irregular. General muscular rigidity develops, especially in the muscles of the spine, producing the positive spine sign and even opisthotonos. Attempts to flex the neck produce pain and cause the patient to bend his knees and hips (Brudzinski's sign). If the leg is flexed at the

hip, the leg cannot be straightened at the knee (Kernig's sign). *The rigidity of the neck and back is frequently absent in very young infants.*

Disturbances of the sensorium are frequent, causing delirium, stupor and even coma. Petechial or purpuric skin lesions are an early characteristic manifestation (Fig. 117). Herpes labialis is common. The *tache cérébrale*, a conspicuous linear mark produced by drawing the fingernail across the skin, indicates a disturbance of the vasomotor mechanism. A tense or bulging fontanel, choking of the optic disks and a positive Macewen sign are evidences of increased intracranial pressure. The last sign is a "cracked-pot sound" elicited by percussion over a distended lateral ventricle. Urinary retention, constipation, anorexia and rapid loss of weight may be clinical features.

The fulminating meningitic form is characterized by an explosive onset and rapid course, terminating in death. The entire course may last only six to forty-eight hours. The attack usually begins with violent headache, chills or convulsions, vomiting and high fever. Delirium or coma appears early, and the skin manifestations are pronounced; massive hemorrhages in the adrenals are associated with profound shock and usually with sudden death (Waterhouse-Friderichsen syndrome, Fig. 118).

Infrequently a meningitic infection may exist for days or weeks before suggestive signs lead to a lumbar puncture. This mild form usually occurs in infants as a sporadic case or near the end of an epidemic. Diarrhea and vomiting are common symptoms. Irritability is usually noted, but meningeal signs may be equivocal. Increased tension of the fontanel or weakness of an external ocular

muscle may be the first clue. Relapses are common in this atypical form.

**Chronic meningitic form.** The clinical course may extend over a long period, usually characterized by emaciation, opisthotonos, hydrocephalus, cranial nerve palsies and by persistence of the Meningococcus in the cerebrospinal fluid. The usual outcome is death, but the illness may last for months. Such clinical patterns are usually the result of delay in starting therapy or of suppressive rather than curative therapy.

**Septicemic form.** The onset is usually sudden, with fever, chills, vomiting and weakness. Skin lesions (Figs. 117, 118) develop rapidly. If meningeal manifestations occur, they usually appear one to three days later. Most often if meningitis does not occur, the course of the septicemic form is rapid, ending either in death or, if therapy is effective, in recovery. In certain instances low grade fever with joint pains and muscular tenderness suggests a grippal infection or acute rheumatic fever, and the proof of meningococcemia by blood culture is unexpected.

**Diagnosis.** In the meningitic form this is by examination of the cerebrospinal fluid, which is usually under increased pressure. The total cell count may range from only a few cells to several thousand per cubic millimeter. The majority of the cells are polymorphonuclear; rarely, at the outset, mononuclear cells may predominate. The protein content is elevated, the sugar content is usually reduced, and the chloride content is diminished. Though purulent cerebrospinal fluid containing intracellular and extracellular gram-negative diplococci is strong evidence in favor of meningococcal meningitis, a definite diagnosis is made only from culture. Samples of the cerebrospinal fluid should be taken in three

FIG. 118. Fulminating type of meningococcemia in a male child 2½ years of age; onset 36 hours before admission, with vomiting and fever; 18 hours before admission extensive purpuric eruption began; death 8 hours after admission. Blood culture positive, Meningococcus type II. Nasal and cerebrospinal fluid cultures negative. One sibling had meningitis; another was found to be a carrier.

sterile tubes: one for cell counting and direct smear, and then placed in the incubator for future reference; the second for determinations of protein, chlorides and sugar; and the third for bacterial culture.

Cultures from the nasopharynx and from the blood are advisable before treatment is instituted. The white blood cell count is usually increased, sometimes as high as 20,000 to 30,000 per cubic millimeter, with a preponderance of polymorphonuclear cells.

**Complications.** *Hydrocephalus* and subdural collections of fluid (see p. 1087) are frequent and important complications. Inability to obtain fluid by lumbar puncture when it is readily obtained by ventricular puncture may be the first indication of basilar obstruction. Unless the obstruction is relieved, either death occurs during the acute period, or hydrocephalus develops.

Other nervous system complications include headache of varying degree which may persist for weeks or months, impairment of the intellectual faculties, chronic pachymeningitis, convulsions and various types of paralyses, spasticity and contractures.

*Otitis media* is common in the acute stage of the infection. Deafness is usually bilateral and usually permanent. It results from infection of the inner ear with or without associated middle ear infection.

*Ophthalmia* occurs in about 5 per cent of cases. There may be an optic neuritis, uveitis or purulent choroiditis which is usually embolic in origin and may lead to destruction of the eye. Fortunately these lesions are usually unilateral. Optic atrophy may result, particularly in association with hydrocephalus. Conjunctivitis is common, and corneal ulcers may develop unless proper precautions are taken.

Arthritis of the large joints may occur, especially during the first week of the disease. *Endocarditis* is most frequently observed in meningococcemia without meningitis. *Pneumonia*, an occasional complication, is usually caused by secondary invading organisms.

**Prognosis.** The death rate from meningococcal meningitis varies considerably in different epidemics. Before the introduction of specific serum therapy the case fatality rate was about 75 per cent; in patients treated with serum, it was about 20 to 30 per cent. The case fatality rate is now less than 10 per cent and is almost entirely limited to the group with adrenal inadequacy (Waterhouse-Friderichsen syndrome). However, recent surveys indicate that the incidence of neurologic

and psychotic sequels may be relatively high.

**Treatment.** Sulfadiazine is the drug of choice, but it is often given in combination with penicillin. Initially, while the cerebrospinal fluid is being examined, an intravenous infusion of equal parts of physiologic saline solution and 5 per cent glucose is started. After hydration has been established an initial dose of sodium sulfadiazine (50 mg. per kilogram) in a 5 per cent solution is introduced through the clamped tube for fifteen to thirty minutes. If the intravenous route is continued, the total daily dose is approximately 150 mg. per kilogram per day in three equal eight-hourly doses. If the oral route is possible, after the initial dose, 200 mg. per kilogram (100 mg. per pound) are given in four to six equally divided doses. In some instances the drug may be given through a gastric tube.

Sulfadiazine should be continued for seven to eight days, during which time blood levels should be determined, the first one twenty-four hours after beginning of therapy. A blood level of 8 to 10 mg. per 100 ml. is ideal and should produce a level of 60 per cent of this amount in the cerebrospinal fluid. Certain reactions to sulfadiazine may be expected, such as fever, rash, renal complications and peripheral neuritis. Determinations of hemoglobin, white blood cell counts and urinalyses should be made every other day. The occurrence of drug eruptions, severe leukopenia, hemolytic anemia or gross hematuria is generally an indication for cessation of sulfonamide therapy and change to penicillin. Adequate hydration and alkalization serve to minimize the likelihood of renal complications.

Procaine penicillin, 300,000 units twice daily for infants and twice this amount for older children, may be injected for the first two or three days.

In circulatory collapse and shock (Waterhouse-Friderichsen syndrome), as indicated by a fall in blood pressure and a decrease in the total eosinophil count, cortisone should be given intravenously (50 mg. for an infant and 100 mg. for a child). If, after one or two doses, there is a favorable response, the drug is continued orally in half the intravenous dose every four to six hours for two days.

Specific antitoxin is no longer used. Two examinations of the cerebrospinal fluid are usually adequate—one for diagnosis and one five to seven days later to check the therapeutic response.

**General supportive treatment.** Symptomatic care is often neglected. Adequate nutrition should be maintained; feeding by gavage is often necessary. Good nursing care serves to prevent the development of bed sores, stomatitis and the excessive drying of the conjunctivas in delirious patients. Distention of the bladder should be avoided, by catheterization if necessary. Excessive headache and restlessness may be relieved by administration of a suitable sedative, such as paraldehyde, or by spinal drainage. Excessive vomiting and fever quickly cause dehydration, which may be prevented or treated by the intravenous administration of 5 per cent glucose and saline. Solutions of amino acids are an efficient means of supplying nitrogen when parenteral feeding is required. Blood transfusions are indicated if the hemoglobin level is less than 9 gm. per 100 ml.

The convalescent period should be adequate to permit the child to regain his previous physical status. Before isolation precautions are discontinued it should be ascertained by culture of the nasopharynx that the child is not a carrier.

#### **STREPTOCOCCAL MENINGITIS**

The hemolytic *Streptococcus* is a relatively frequent cause of purulent meningitis, especially in the first six months of life. In the newborn infant the *Streptococcus* may gain entry to the blood through a superficial infection, such as an umbilical one, or may reach the meninges directly through an infected meningocele. In older children otitis media, mastoiditis, sinus thrombosis, erysipelas or suppurative lesions of the head and scalp may constitute the portal of entry.

Anatomically, there is a considerable amount of purulent exudate over the surface of the brain, resembling that of pneumococcal meningitis except that there is somewhat less fibrin in the exudate.

Streptococcal meningitis cannot be distinguished from other types of purulent meningitis except by bacteriologic examination of the cerebrospinal fluid, which should be made immediately if a meningeal infection is suspected.

**Treatment.** Treatment should be instituted at the earliest possible moment. Penicillin is the drug of choice and may be administered alone or in conjunction with a sulfonamide (see p. 402). Other antibiotics such as chloramphenicol and the tetracyclines are effective, but, except in the ex-

tremely rare instance of penicillin-resistant beta-hemolytic streptococci, penicillin is preferable. It is always desirable to obtain determinations in vitro of the relative sensitivity of the infecting organism to the various antibiotics.

Whenever there is any question of a significant mastoid involvement, the mastoid should be opened and, if indicated at operation, the dura exposed. If there is early and adequate medical and surgical care, the mortality rate should not be more than 10 per cent.

#### **PNEUMOCOCCAL MENINGITIS**

Pneumococcal meningitis is more prevalent among infants than among older children. The seasonal distribution is similar to that of pneumococcal pneumonia, of which it is an important complication. There may frequently be a history of pneumonia, upper respiratory infection or infection of the middle ear. Trauma, particularly fracture of the skull, may be a predisposing factor. Infection of the blood stream is frequent.

**Etiology.** Any of the specific types of *Pneumococcus* may be responsible for pneumococcal meningitis, but types III, V and XIV appear to be the more common ones.

**Pathology.** The lesions of the brain and meninges resemble those produced by the *Meningococcus*. The heavy exudate of pus and fibrin may be more abundant over the anterior lobes and less marked over the basilar areas of the brain. For this reason spinal rigidity and opisthotonos may be slight or absent. The spinal meninges are usually only slightly involved.

**Diagnosis.** The clinical manifestations do not differ from those of purulent meningitis caused by other pathogenic bacteria. The diagnosis depends upon the bacteriologic findings. The cerebrospinal fluid is purulent, containing many polymorphonuclear cells and gram-positive lancet-shaped diplococci which are usually easily recognized on direct smear and easily cultured on blood-agar medium. The sugar and chloride contents of the cerebrospinal fluid are decreased and the protein increased.

**Complications.** As with other purulent meningitides, the decreasing case fatality rate has been associated with a definite increase in serious complications, many of which are permanent and severely handicapping. There may be a variety of pneumococcal lesions outside the nervous system such as empyema,

FIG. 119. L. C., female, 6 months of age. *H. influenzae* meningitis. Onset 5 days before admission, with cold and diarrhea (2 siblings with "grippe"). One day before admission, fever, vomiting, irritability, stiff neck, full fontanel. No organisms seen in initial smear of cerebrospinal fluid; hence 3 million units of aqueous penicillin were injected daily for 2 days. Complete recovery.

pericarditis, peritonitis and arthritis, but the more frequent and usually more important ones involve the central nervous system.

**Prognosis.** Most patients can and do survive. Both survival and the extent of residual damage are related to the promptness of instituting therapy and to its adequacy.

**Treatment.** Penicillin is the drug of choice, but many clinicians also use sulfadiazine in conjunction with it.

Because the blood-brain barrier is higher for penicillin than for sulfadiazine or chloramphenicol, total doses of two to twelve million units of the aqueous crystalline form are given daily by continuous intravenous drip for the first three days. After this, procaine aqueous penicillin is continued intramuscularly in doses of one million units twice daily.

Sulfadiazine is given in an amount to maintain a blood level of 10 to 15 mg. per 100 ml. (see Meningococcal Meningitis, p. 428).

Chloramphenicol is sometimes added to the penicillin-sulfadiazine regimen. The total daily dose is 100 mg. per kilogram intramuscularly, or 200 mg. orally.

All therapy is discontinued after eight to ten days, provided the clinical and cerebrospinal fluid findings are satisfactory. There is no indication for specific antiserum therapy.

Adequate fluid intake must be maintained. Sedation should be prescribed as indicated, but depression of the respiratory mechanism

should be avoided. Early surgical drainage of foci, such as those of otitis media and mastoiditis, is indicated.

### INFLUENZAL MENINGITIS

**Etiology.** *Hemophilus influenzae* is a common cause of bacterial meningitis in infants. The strains causing meningitis are serologically related and are included in the group termed type b. In most instances the disease is preceded or accompanied by an infection of the upper respiratory tract which frequently includes involvement of the middle ear. Influenzal meningitis is essentially a disease of infancy, the peak of incidence occurring between six and twelve months of age. It is rare during the first two months of life and infrequent after the fourth year.

**Clinical Manifestations.** The clinical pattern of influenzal meningitis is essentially that of any other type of purulent meningitis. Though bacteremia is usually present, skin manifestations are rare. The cerebrospinal fluid rapidly becomes purulent, and in most instances the organism is readily identified. Infrequently in untreated cases for a short time and frequently when therapy has been suppressive rather than curative, the cerebrospinal fluid changes may be those of a lymphocytic type of response simulating tuberculous meningitis. The presence of gram-negative, pleomorphic, coccobacillary organisms in the direct smear of the sediment should suggest *H. influenzae*. Direct typing of the organisms from the cerebrospinal fluid may be made. The organism is easily cultured on a medium consisting of chocolate agar.

**Complications.** Many complications of influenzal meningitis, but not all, seem to be related to delay in starting therapy, inappropriate selection of therapeutic agents or the use of appropriate agents in too small amounts for too short a time. Complications of the central nervous system include paralysis, mental retardation, nerve deafness and hydrocephalus. Subdural collections of fluid appear to be a factor in the production of some of these (see pp. 428, 1087).

**Prognosis.** Before the advent of effective antibacterial agents the mortality rate approximated 95 per cent; now the recovery rate should be about 95 per cent. However, the incidence of serious and permanent complications has increased markedly.

**Treatment.** A combination of chloramphenicol and sulfadiazine appears to be the therapy of choice. After an initial intravenous administration of 50 mg. of chloram-

phenicol per kilogram of body weight (25 mg. per pound) a dose of 100 mg. per kg. per day is given orally in four equal doses or through a nasal polyethylene catheter if the infant will not swallow. However, if the child is vomiting or if there is any question of gastrointestinal absorption, administration by the intravenous route should be continued at intervals of six hours in individual doses of 25 mg. per kilogram.

Sulfadiazine (0.2 gm. per kilogram per day) orally will usually maintain the desired blood level of 10 to 12 mg. per 100 ml.

Therapy should be continued for at least five to seven days after the temperature has become normal.

Streptomycin and sulfadiazine are also effective, but not more so than chloramphenicol. The recommended dose of streptomycin is 40 mg. per kilogram of body weight (20 mg. per pound) per day in four intramuscular injections. Streptomycin should not be administered for longer than one to two days, owing to danger of vestibular damage. The administration of sulfadiazine should be continued and chloramphenicol added as indicated above.

There now appears to be little indication for the use of specific antiserum. General therapeutic measures are enumerated under Meningococcal Meningitis (see p. 429).

#### STAPHYLOCOCCAL MENINGITIS

Staphylococcal meningitis is usually blood borne from such primary foci as cutaneous lesions (especially in newborn), otitis media, mastoiditis, sinusitis or sinus thrombosis. The infection may also be introduced at the site of a wound or from a surgical operation on the brain or meninges. There is widespread inflammation of the pia with a heavy accumulation of pus and frequently localized abscesses of the brain and meninges.

*Diagnosis* depends upon examination of the cerebrospinal fluid, in the sediment of which the organisms are usually numerous. The culture is confirmatory.

Prior to 1938 only nine recoveries had been reported; now the recovery rate is approximately 40 per cent.

*Treatment.* A combination of penicillin, sulfadiazine and chloramphenicol constitutes good initial therapy and is adequate in most instances. Aqueous penicillin in a daily dose of 12,000,000 units should be given intravenously for three to five days and continued intramuscularly in doses of one million units twice daily for another week. Sulfadiazine

and chloramphenicol are used as prescribed for *H. influenzae* meningitis.

Owing to the high incidence of strains of *Staphylococcus aureus* resistant to all available antibiotics, sensitivity studies should be obtained on the initial culture and repeated if the infection is not controlled or if there is a relapse. Under such circumstances antibiotics shown to be effective against the particular strain by tests in vitro should be selected. These might include erythromycin, novobiocin, and even bacitracin if no other agent is effective.

**TETANUS**

(LOCKJAW)

The systemic manifestations of tetanus are caused by the powerful exotoxin, liberated during the actively growing phase, of *Clostridium tetani*, a spore-forming organism. Like diphtheria, the infection remains localized. Infection is almost always acquired from a contaminated wound.

**History.** Tetanus was produced experimentally before the organism was isolated in pure culture. In 1884 Carle and Rattone transmitted it to rabbits by inoculation of material from an acne pustule that represented the nidus of a fatal human case, and Nicolaier produced a tetanus-like disease in mice, guinea pigs and rabbits by inoculating them with suspensions of dirt. Nicolaier suggested that the disease was carried by organisms that multiplied locally and produced a strychnine-like poison. Kitasato (1889) isolated the organism in pure culture by heating pus to a temperature of 80° C. for forty-five to sixty minutes. Von Behring and Kitasato (1890) demonstrated that tetanus toxin was antigenic, capable of producing antitoxin.

**Etiology.** *Clostridium tetani* is an anaerobic, spore-bearing organism, widely distributed in soil in many parts of the world. The bacillus is frequently found in the intestinal tracts of herbivores and, at times, of man. Under suitable conditions the tetanus bacillus produces several poisons: a lysin for red blood cells, a substance injurious to leukocytes and a neurotropic toxin (tetanospasmin) which produces muscle rigidity and spasms. Unlike diphtheria toxin, tetanus toxin produces no skin reaction suitable for the assessment of immunity.

**Epidemiology.** Tetanus occurs most frequently in areas where soil contamination is heavy and standards of cleanliness and care of wounds are poor. It is rare in the newborn infant when aseptic obstetrics is practiced, but otherwise it constitutes a serious problem. In 1950, 486 cases were reported in the United States with 336 (69 per cent) deaths. During World War II active immunization of the personnel of the armed services with toxoid almost completely prevented its occurrence (eight cases with three deaths).

**Pathogenesis.** There is no typical wound that gives rise to tetanus. It may result from the most trivial scratch or insect bite, and the portal of entry is often not apparent. Injuries most likely, however, to lead to

tetanus are deep puncture wounds, because they afford ideal anaerobic conditions, and crushing wounds and burns, because they provide necrosis of tissue. The site of infection has been reported in the tonsil, the alimentary tract and in ocular and aural lesions. A number of cases have resulted from the use of contaminated catgut and serologic products. Though tetanus occasionally results from smallpox vaccination, it is practically always due to improper care of the secondarily infected lesion rather than to contaminated virus.

The manner of absorption and the mode of action of the toxin have been the subject of considerable controversy. There are two main hypotheses: (1) that the toxin is absorbed at the motor nerve endings and reaches the anterior horn cells of the central nervous system by means of the axis cylinders; and (2) that the toxin is absorbed by the lymphatics and distributed to the central nervous system by the arterial blood supply. After the toxin has become fixed to nerve tissue, it apparently is not easily neutralized by specific antitoxin, but it is in its free, circulating form.

**Immunity.** Immunity to tetanus may be natural or acquired. Mammals vary in their susceptibility. The blood of naturally resistant animals contains practically no antitoxin; hence their immunity cannot be humoral. Persons of all ages are susceptible. The proportion of cases among adults has gradually increased. In Massachusetts (1954) more than half of those over twenty years of age had antibody levels of less than 0.01 unit; women had lower levels than men. The newborn has placentally transmitted antitoxin, but it is usually inadequate for protection.

The toxin is highly antigenic, and the prophylactic and therapeutic use of its specific antitoxin is of tremendous practical importance. It acts by neutralizing toxin, but does not prevent the germination of spores or multiplication of the bacilli in tissue. Modification of the toxin into toxoid by treatment with formalin affords a potent antigen for the production of active immunity.

**Clinical Manifestations.** The incubation period is usually five to fourteen days, but may be prolonged to several weeks in mild infections or when the course has been modified by antiserum.

The clinical manifestations of tetanus are usually generalized, but occasionally may be localized to the area of injury. Localized manifestations are usually the result of in-

complete neutralization of toxin elaborated in the area of the injury with complete neutralization of that in the blood. The action of the toxin in such instances is on the motor end organs, resulting in localized spasm and rigidity.

The onset of the generalized form is usually insidious, with increasing degrees of muscle stiffness, especially those of the jaw and neck. Within forty-eight hours the disease is well defined, and difficulty in opening the mouth (trismus) is evident. Difficulty in swallowing, restlessness, hyperirritability, headache, chilliness, and pain in the extremities are early symptoms. A clonic convulsion, caused by the effect of toxin on the anterior horn cells, is often the first symptom. Rigidity of the abdominal muscles may suggest the possibility of an acute intra-abdominal lesion.

The spasm is characteristic. The body exhibits boardlike rigidity, while the head is drawn back in pronounced opisthotonos with legs and feet extended. The arms are stiff and the fists clenched. The spasm of the facial muscles results in a fixed expression (the sardonic grin, or *risus sardonius*). The eyebrows are raised, and the mouth is distorted by the downward and outward drawing at the angles. The patient is apprehensive. The spasms at first are intermittent and often separated by apparently complete relaxation. Later the periods of relaxation are less obvious, and the seizures become painful. Intramuscular hemorrhage may result from violent contractions. Cyanosis and asphyxia may result from paroxysms affecting the respiratory or laryngeal muscles. Convulsions may be precipitated by the slightest stimulus, such as handling the patient, attempts to drink or even by visual or auditory stimulation. Profuse sweating is common. Retention of urine may be due to spasm of the urethral muscles. In rare instances spasms may be sufficiently severe to cause compression fractures of the spine; hence roentgenographic examination of the spine of patients who have had unusually long and severe spasms should be obtained before they are permitted out of bed.

Fever is usually of a low grade, except that there is often a marked elevation during the terminal stage. Respirations are variable in rate and depth, and the pulse rate is increased. The cerebrospinal fluid is normal, but under some increase of pressure. There is usually a moderate leukocytosis.

**Diagnosis.** The diagnosis usually offers little difficulty. The history of a wound and the characteristic type of muscular spasticity,

particularly of the jaw, are fairly conclusive. In infants other convulsive disorders may be confusing. Spasms due to strychnine rarely involve the jaw muscles and are interspersed by periods of more complete relaxation. Tetany may be recognized by chemical studies of the blood. Meningitis may be identified by examination of the cerebrospinal fluid. Tetanus is probably the only condition likely to be confused with rabies. The history of a bite, mental excitement, constant pharyngeal and laryngeal spasm, absence of trismus, and pleocytosis of the cerebrospinal fluid are distinguishing features of rabies. Local causes of stiffness of the jaw, such as enlarged cervical lymph nodes and retropharyngeal abscess, should easily be recognized.

**Prognosis.** The general mortality rate is still high (20 to 50 per cent). Fatal cases usually terminate within a week or so and are more frequent after short incubation periods. A period of less than forty-eight hours between the first symptom and the first spasm is prognostically unfavorable. Uncontrolled seizures, respiratory complications and grossly contaminated wounds contribute to an unfavorable outcome. Mortality rates are highest in newborns and in the aged. Most deaths are precipitated by respiratory conditions such as obstruction by secretions, asphyxia from laryngeal spasm, prolonged anoxia, atelectasis and pneumonia. The judicious use of tracheotomy appears to have facilitated the management of these complications.

**Prevention.** The prevention of tetanus consists to a considerable degree in the prevention of injuries; it is, in part, an educational endeavor, which should include children. Most communities have legislation to control the sale of fireworks. Competent surgical care of wounds is essential.

The injection of antitoxin within a few hours of the receipt of a wound produces *passive immunization* and prevents tetanus or lengthens the incubation period and results in a milder type of disease.

The generally recommended prophylactic dose of antitoxin is 1500 to 5000 units injected subcutaneously after a preliminary skin test to determine sensitivity to the serum, but some give as much as 10,000 to 20,000 units. The difficulty of deciding when antitoxin should be used, the fear of anaphylaxis, the induction of serum sensitivity and the occurrence of tetanus even when passive immunization has been carried out are all practical objections to this form of prophylaxis.

Glaser emphasizes the advantage of the use of bovine antitoxin, particularly for the passive immunization of allergic children. The administration of penicillin for two or three days following a severe injury may be an *additional* preventive factor because of its bactericidal effect.

When antitoxin is given to a child who has not had active immunization, it should be considered obligatory to give tetanus toxoid within the next few weeks.

*Active immunization* offers an excellent possibility of reducing the incidence of tetanus. Alum-precipitated, aluminum hydroxide-absorbed, and fluid toxoids are available. Though each is definitely antigenic, alum-precipitated and aluminum hydroxide-absorbed toxoids produce more durable immunity than does fluid toxoid. On the other hand, fluid toxoid produces a more rapid secondary response and therefore is the choice for a booster injection after a wound.

For basic immunization, three primary injections of toxoid at intervals of one to three months are advised, with subsequent booster injections (see p. 141). A severely wounded immunized person, or one in whom the last injection of toxoid was made four or more years previously, is afforded maximal prophylaxis by the simultaneous injection of both antitoxin and fluid toxoid in different extremities.

**Treatment.** Constant attention to the general care and supportive measures are essential. The patient should be kept in a quiet room, and external stimulation should be avoided. Oral and gastric feeding should be deferred until the dangers of vomiting and aspiration no longer exist. Proper and immediate surgical care of the wound is important.

**Sedatives.** The ideal sedative would be one capable of controlling spasms and convulsions without respiratory depression. Unfortunately, this requirement is not easily met. Paraldehyde given rectally is one of the safest and most effective sedatives. Avertin (tribromoethanol amylene hydrate) administered rectally in doses of 10 to 15 mg. per kilogram (5 to 7 mg. per pound) is effective, but, since it is a respiratory repressant, its effect must be carefully watched. Spivey considers phenobarbital in individual doses of 15 to 30 mg. by gavage to be the most satisfactory sedative in tetanus neonatorum.

Curare and related drugs should be used only when the spasms cannot be controlled

by the usual measures, and then only by experienced personnel.

Since death is often related to respiratory obstruction, the performance of tracheotomy may be lifesaving and should be carried out when pulmonary ventilation is impaired. Oxygen and the use of the respirator may be required.

Penicillin should be given every twelve hours for its probable effect on *Cl. tetani* and to control secondary infection. Other antibiotics should be given when indicated to control specific secondary invaders.

**Serum therapy.** Antitoxin is the only specific agent. Fifty thousand units intramuscularly and 50,000 units intravenously should be given immediately. After the intravenous administration of antitoxin 5000 to 10,000 units may be infiltrated around the wound in preparation for wide excision, if indicated. The wound should be left open. Firor advises daily intramuscular injections of 5000 units to assure the maintenance of sufficient humoral antibody.

Active immunization should be started during convalescence.

## BACILLARY DYSENTERY

### (SHIGELLOSIS)

Bacillary dysentery is caused by a variety of closely related organisms and involves chiefly the large bowel. It is characterized clinically by fever, general toxicity, abdominal pain, tenesmus and frequent loose stools containing mucus, pus and blood.

**History.** Hippocrates is said to have distinguished diarrhea from dysentery by associating the former with the frequent passage of liquid stools and the latter with the passage of bloody stools. In 1898 Shiga isolated a gram-negative bacillus from the feces and intestinal wall of dysenteric patients in Japan. His work is an outstanding example of the use of the agglutination reaction of the patient's serum to discover the causative agent of a disease. In 1900 Flexner isolated several strains of dysentery-producing organisms in the Philippines, and in 1915 Sonne described *Shigella sonnei*, an organism which he isolated in Denmark.

**Etiology.** The *Shigella* group of organisms (*Enterobacteriaceae*) is an important cause of diarrhea. Organisms of this genus are nonmotile, gram-negative, nonencapsulated and nonspore-forming rods. All are easily killed by heat, sunlight and ordinary disinfectants. Although earlier methods of differentiation were based upon biochemical reactions, serologic methods are now more generally used.

Upon the basis of biochemical and antigenic characteristics, Cheever suggests the following classification of the more important *Shigellae*:

Group A. *Shigella dysenteriae* (Shiga) is the most important member. It is prevalent in tropical countries and in East Asia and is occasionally encountered in the United States, where the case fatality rate is approximately 10 per cent.

*Shigella ambigua* (the Schmitz bacillus) has been chiefly associated with institutional outbreaks in the United States. Its distribution is worldwide.

*Shigella large sachsii*, described chiefly by Sachs in India, has been reported from North Africa and the United States.

Group B. *Bacillus dysenteriae* Flexner (Flexner bacillus), also called *Sh. paradyenteriae*, causes a significant proportion of dysentery infections in this country. It contains at least six different type-specific strains; in addition, many strains contain secondary antigens common to others.

Group C. *Bacillus dysenteriae* Boyd was first isolated in India in 1930; at least seven specific types of the organism have now been identified.

Group D. *Shigella sonnei* (Sonne-Duval bacillus), one of the important causes of diarrhea in the United States, is worldwide in distribution. Two antigenic types have been recognized.

*Shigella alkalescens* and *Sh. madampensis*, sometimes considered to be pathogenic, are regarded by some authorities as members of the genus *Escherichia*.

**Epidemiology.** The prevalence of shigellosis varies with such factors as climate, living conditions and age. Studies of the presence of shigellae in the normal population reveal rates varying from 0.04 per cent in New York City to 20 per cent in certain southern areas of the United States. In a series of 2865 routine admissions to a children's hospital (Cincinnati, 1954-56; Cooper) rectal swab cultures were positive for *Shigella* in eighty-eight, for *Salmonella* in eighty-five, and for pathogenic *E. coli* in 188. Practically all patients with any of these organisms had diarrhea.

Explosive epidemics are not common, but small outbreaks are frequent. Crowding in institutions and summer camps under conditions of poor sanitation offer favorable conditions for an outbreak. Poor refrigeration

and food contaminated with soil or by flies that have access to human excrement are important factors. Unlike typhoid, bacillary dysentery is seldom water-borne. There is some evidence that there is a lesser tendency to a peak incidence in summer and fall, that the disease is becoming more urban than rural and that the incidence among older children is increasing.

Shigellosis is almost entirely a disease of human beings. The mode of spread is from man to man in which the carrier is highly important. In untreated cases the carrier state may last for a month. Ordinarily carriers of the Shiga type are more persistent than those of the Flexner type. The organism may be excreted intermittently, a factor which adds to the difficulty of detecting it by culture.

*Shigella* infection varies with age. Its prevalence is low during the first six months of infancy, increases during the next six months to a level which is maintained for several years. The disease is often severe, frequently fatal, in early infancy, but less severe and often mild after three years of age.

**Pathology.** Unlike typhoid fever, dysentery is a local infection which chiefly involves the colon. In about half or less of the cases the lower ileum is affected, where the lesions are usually less severe.

The mucosa of the intestine is thickened, hyperemic, inflamed and edematous; it may be covered by patches of fibrinopurulent exudate. Shallow ulcers are present which vary greatly in size; these seldom penetrate below the submucosa, and perforation is rare. Healing of the ulcers is usually complete. The mesenteric lymph nodes are somewhat enlarged, but the spleen is not involved.

**Clinical Manifestations.** The incubation period may vary from a few hours to eight days, but is most frequently two to four days. The symptoms and signs are readily explained by the pathologic changes. The pain, tenesmus and diarrhea result from acute inflammation of the bowel; the mucus, pus and blood, from inflammation of the bowel epithelium. Since the disease is characteristically localized, septicemia and splenic enlargement are rare. Toxic encephalitis and peripheral neuritis occur occasionally in *Shigella* infections, and somewhat less often in Flexner infections.

The clinical severity of dysentery may vary from extreme mildness to such severity that death occurs on the first day. In the *mild* cases there may be practically no constitutional symptoms. Instances with little or no diarrhea have been recorded.

The onset of the usual case of dysentery is sudden with fever, vomiting and frequently abdominal pain. The temperature is usually high, 102° to 105° F. Meningeal signs are frequent. The passage of frequent, loose, thin stools within six to twenty-four hours of the onset which later contain mucus, pus and streaks of bright red blood suggests the diagnosis. The number of stools varies, but ten to twenty a day is average. Abdominal cramps usually precede a passage, which is often accompanied by tenesmus. In some instances tenderness may be elicited by palpation along the course of the colon. There may be weakness, delirium and rapid loss of weight due to dehydration.

The acute symptoms usually last five to ten days. The temperature tends to return to normal as the stools become formed. In some instances normal stools may not be noted for two to three weeks after the onset.

The onset of the *toxic*, or most severe, form is usually even more abrupt, and all the symptoms are exaggerated. The temperature is high, often septic in type, and diarrhea is severe. Tenesmus and often prolapse of the rectum are present. Sunken eyes, dryness of the mucous membranes, coating of the tongue and sordes of the lips and teeth indicate rapid loss of body fluids. Acidosis develops rapidly. Delirium, weakness and convulsions may occur. Abdominal distention in association with a decrease or cessation of bowel movements is an unfavorable situation.

In some instances the infection becomes *chronic*, persisting for weeks or months. The fever is of the low grade type, or the temperature may even be subnormal. The course is characterized by remissions of the diarrhea, the stools containing large amounts of mucus, but little or no blood. Continued poor nutrition, progressive loss in weight, and feeding difficulties are characteristic, and there may be abdominal distention, secondary anemia, nutritional edema and vitamin deficiencies. In such instances sigmoidoscopic examination may reveal a diffusely injected granular mucosa with follicular ulceration, cultures from which frequently reveal dysentery organisms.

**Diagnosis.** The majority of patients with an acute febrile disease associated with loose stools containing gross or microscopic blood, mucus and leukocytes have dysentery. Atypical cases, such as the chronic type, and acute cases in the prediarrheal stage, pose more difficult diagnostic problems. A mild diarrhea without mucus, blood or pus, due to *Shigella* organisms, is fairly common.

The diagnosis depends upon isolation of the organism from the stool or from material obtained by rectal swab. The culture should be made immediately, since the organism dies rapidly upon drying. A highly selective medium such as SS agar (*Shigella*-*Salmonella* thiosulfate citrate bile) is used. Suspicious colonies are transferred to carbohydrate broths (lactose, glucose, mannitol, xylose, and the like) for detection of characteristic fermentation reactions. The organism is also tested for indole and hydrogen sulfide production and for motility. Finally, it is agglutinated with polyvalent and later monovalent antisera.

**Differential Diagnosis.** *Typhoid fever* and other types of *Salmonella* infection may closely resemble bacillary dysentery. *Amoebic colitis* may be differentiated by identifying *Entamoeba histolytica*.

*Intussusception* in its early stage may be mistaken for dysentery. The onset with spasmodic pain and recurrent vomiting, the appearance of an abdominal mass and the shock-like symptoms of intestinal obstruction should distinguish it.

Occasionally there is localization of abdominal pain over the cecum, with tenderness and a delay in the appearance of diarrhea. When there is a moderate leukocytosis, *acute appendicitis* must be considered, and removal of the appendix often is a justifiable, although not profitable, procedure under the circumstances. Mesenteric adenitis is frequently observed at operation, and diarrhea may appear the next day.

Bleeding from focal lesions such as *Meckel's diverticulum*, *papilloma* or *duodenal ulcer* is usually not associated with the passage of frequent stools. Roentgenographic studies may aid in identification.

In the prediarrheal stage of dysentery meningeal and encephalopathic symptoms are frequently present. *Meningitis* or the pre-paralytic stage of *poliomyelitis* may be suspected, and a lumbar puncture may be necessary for diagnostic purposes.

**Complications.** Pneumonia and otitis media are occasional complications, especially in infants. Invasion of the blood stream by the dysentery organism is rare; pyelonephritis is uncommon. Dural sinus thrombosis and venous thromboses have been observed, principally with severe dehydration; encephalitis and peripheral neuritis are rare and usually not permanent residuals. A late complication, more frequently encountered in adults, is nonsuppurative arthritis, particularly of the

knee joints. Vaginitis may occur, but is not common. Dietary deficiencies are frequently observed in the chronic cases.

**Prognosis.** A certain degree of durable immunity appears to follow an attack of the disease. Whether this protection extends beyond group specificity is not established. Second attacks probably represent relapses occurring in a carrier. The disease usually lasts one to six weeks. The case fatality rate is high among infants. Death from toxemia occurs early in the disease; later in the disease it usually results from fluid imbalance and acidosis. Pre-existing malnutrition and concomitant infections are contributory factors to an unfavorable outcome. Infection caused by the Sonne organism is seldom fatal, but that caused by the Shiga organism is most serious. The case fatality rates vary considerably.

**Prevention.** The proper care of food and thorough washing of food which has been in contact with soil are important measures. The child with dysentery should be isolated and protected from flies. The carrier should be subjected to the same precautions as in typhoid fever, although chemotherapy appears to be more effective among dysentery carriers. There is no effective method of active immunization.

**Treatment.** The important aspects are prevention and control of water and electrolyte imbalance, chemotherapy and diet.

The treatment of dehydration by maintaining the proper fluid and electrolyte balance is of the greatest importance, especially in infants. In the more severe cases an initial period (twenty-four to seventy-two hours) of elimination of oral feeding during which parenteral fluids are administered may be desirable (see p. 186). Only small amounts of glucose and saline solution are given orally during this phase. After this time other fluids can usually be given orally. Skimmed lactic acid milk containing scraped raw apple, apple powder, apple pectin-agar or pectin-kaolin mixtures is usually well taken, and banana powder may be added shortly, or fully ripe bananas may be given separately. High-protein, low-residue diets are as a rule well tolerated. Separate administration of all the vitamins in fairly large amounts is indicated. During the postdysentery period, feeding may be extremely difficult, and occasionally gavage may be necessary.

The sulfonamides are effective in most instances. There now appears to be general agreement that the readily absorbed drugs

such as sulfadiazine and Gantrisin are more effective than the poorly absorbed ones. Doses are in the range of 120 mg. per kilogram (60 mg. per pound) in four equal doses. When there is vomiting, the drug may be given intravenously or subcutaneously as its sodium salt until oral medication is possible. Chloramphenicol and the tetracyclines are also effective. Length of treatment varies and should be dependent on control of symptoms and eradication of the dysentery organism, which can be expected in the acute cases within four to seven days.

Paregoric is often indicated to relieve pain and tenesmus, and it may reduce the number of stools. Repeated colonic irrigations are harmful. In Shiga infections antitoxin is indicated if it can be injected early in the course of the disease.

## TYPHOID FEVER

### (ENTERIC FEVER)

Typhoid fever is an acute, generalized febrile disease caused by the typhoid bacillus (*Salmonella typhosa*). Though the portal of entry is the gastrointestinal tract, many of the essential features of the disease depend upon the occurrence of early bacteremia.

**History.** The intestinal lesions were described by Bretonneau in 1820; Louis described the disease and named it *fièvre typhoïde* in 1829. One of his pupils, Gerhard, observed an epidemic of typhoid and one of typhus fever in Philadelphia in 1837 and gave a clear clinical differentiation of the two diseases. Badel (1873), another pupil of Louis, emphasized the importance of feces as a source of the infecting agent and described the danger in the excretions of a convalescing patient, as well as the

FIG. 120. Illustrating the time relationships in typhoid fever of the occurrence of positive blood and stool cultures and agglutinins in the blood serum. (Topley and Wilson: Principles of Bacteriology and Immunity. Edward Arnold & Co.)

role of water and milk in the spread of the disease.

In 1880 Eberth discovered the causative agent, and in 1896 Widal discovered the agglutination reaction. Russell (1909) used vaccine for the prevention of typhoid fever in the United States Army.

**Etiology.** *Salmonella typhosa* is a gram-negative, motile, nonspore-forming bacillus. It may be easily isolated from the blood during the early stage of the disease, and later from the urine and feces. During the bacteremia it may be found in the spleen, bone marrow, lymphatics and gallbladder. During the second week of the disease specific agglutinins appear in the blood serum.

The bacillus has at least three types of antigens, the "H" (flagellar), the "O" (somatic) and the "Vi." Agglutinins against the "H" antigen result from a previous typhoid infection or vaccination. A high titer of agglutinins against the "O" antigen denotes active infection. The blood of chronic carriers usually contains "Vi" antibodies, but the antigen is not available for practical use. It has been suggested that "H" antibodies may have little protective value, while the "O" and the "Vi" are important from this standpoint. In general, an agglutination titer of 1:160 or higher against a formalinized suspension of typhoid bacilli is significant. A progressively rising titer in subsequent tests is diagnostic. In most cases of typhoid the "O" agglutinins appear

earlier than the "H," and agglutination for them is therefore preferred in performing the Widal test. In the macroscopic method the "O" type produces a small, granular flaky reaction; the "H" type produces a large flaky one.

The rise in the agglutinin titer of the serum is usually associated with a decreasing bacteremia (Fig. 120). The time when the titer reaches its maximum frequently coincides with clinical improvement.

**Epidemiology.** Typhoid fever is a preventable disease and does not exist to a significant degree where rigid rules of sanitation prevail. The most important source of infection is the human typhoid carrier.

Water-borne and milk-borne epidemics are characterized by explosive onsets. One of the most serious epidemics, traceable to a contaminated milk supply, occurred in Montreal in 1927. Between March and July, 4849 cases with 489 deaths occurred. Other food-stuffs, such as ice cream, butter, cheese and shellfish, have been responsible for outbreaks.

The disease is found in practically all parts of the world; in the temperate zones it is more prevalent during the late summer, fall and early winter months. It is typically a disease of childhood and early adult life, occurring most frequently between the ages of fifteen and thirty years. It is fortunately rare

in infancy, when the mortality rate is high.

**Immunity.** Two of the immunologic aspects, the relapse and the so-called permanent immunity, are difficult to explain. The disease may continue or even relapse in the presence of an appreciable concentration of humoral antibodies. Organisms in such instances probably disappear from the blood and remain in the spleen, lymph nodes or other locations where they are protected from the action of antibodies in the serum, but where they liberate toxic factors.

In explanation of permanent immunity to typhoid infection, it is postulated that the tissues of a previously infected person probably remain highly sensitized even though the humoral antibodies have disappeared, and, when reinfected, respond to the antigenic stimulation with the immediate production of humoral antibodies sufficient to prevent another attack.

**Pathogenesis.** The bacillus enters the body tissues through the walls of the alimentary tract. In the blood stream and particularly in the reticuloendothelial cells of the liver and spleen the organisms are destroyed by phagocytosis. In these organs the bacilli also multiply rapidly and secondarily reinfect the blood stream. It has been suggested that the beginning of the second phase represents the clinical onset of the disease. Large numbers of organisms are eliminated from the liver, and heavy secondary infection of the intestinal tract occurs. In this manner the gallbladder is also readily infected and becomes the nidus of the chronic carrier.

The general symptoms of the disease, such as fever, malaise and headache, are caused by the action of toxins. Bacterial emboli in the capillaries of the skin produce the characteristic rose spots. The splenomegaly is caused by congestion of the splenic pulp, by the great accumulation of red blood cells and by endothelial hyperplasia. Ulceration of the bowel accounts to a great degree for the intestinal symptoms. The leukopenia results from the action of toxins on the bone marrow and from its overcrowding by great numbers of phagocytic endothelial cells.

**Pathology.** The lymphoid tissue of the small intestine, particularly of the lower part of the ileum, is one of the initial sites of infection. Peyer's patches become swollen, and necrosis of the mucosa occurs. The necrotic mucosa sloughs, leaving a round or oval ulcer with the long diameter in the long axis of the bowel; hemorrhage and perforation may occur.

The mesenteric lymph nodes become swollen, soft and hemorrhagic. In the intestinal lymphoid tissue, in the lymph nodes and in the bone marrow there is a nonsuppurative cellular reaction composed chiefly of large phagocytic cells from the reticuloendothelial system. These phagocytes contain lymphocytes, red blood cells and other elements. Polymorphonuclear leukocytes and eosinophils are scarce.

The spleen is enlarged, red and soft. The pulp contains great numbers of red blood cells and large phagocytes, and there are areas of focal necrosis. There are also focal necrosis of the liver and cloudy swelling of the liver and kidneys. The bacillus grows readily in bile and invades the wall of the gallbladder, where there are mild inflammatory lesions. Typhoid infection of the gallbladder may lead to establishment of chronic residual infection (carrier state) and to the subsequent formation of gallstones.

Toxic myocarditis is a common finding. Thrombosis of the veins is frequent and occurs particularly in the femoral and saphenous veins. Zenker's degeneration of muscle occurs frequently. Typhoid meningitis, which is purulent and has a high fatality rate, is rare. Chronic inflammatory changes may occur in the bones—the tibia, sternum, ribs and vertebrae being usually involved. The lesions consist of periostitis, abscess or necrosis and contain typhoid bacilli. Bronchopneumonia is usually caused by a secondary infection.

**Clinical Manifestations.** *In children.* The clinical course of typhoid fever from the second year of life through childhood is similar to that in adults, except that it is usually less severe. The incubation period has been reported to vary from three to forty days, but is usually between ten and twenty. It is said to be longest in water-borne, shorter in milk-borne and shortest in food-borne infections. The entire course of the infection is usually not more than two or three weeks; occasionally the febrile period lasts but one week. The temperature curve is more irregular than in adults, and the disproportion between the height of the fever and the pulse rate is not so constant. There is also a less degree of hypotension, and the dicrotic pulse is often not discernible. The onset may be either insidious or abrupt and often resembles an upper respiratory infection. Disturbances of the sensorium and prostration are less frequent and, when present, less pronounced. The intestinal symptoms are usually less severe than in adults. Tympanites tends to be

moderate and is often associated with abdominal tenderness. Diarrhea occurs in about half of the cases. The stools are liquid and contain mucus. About the end of the first week the spleen becomes enlarged and tends to remain so until the temperature becomes normal, or longer in event of a relapse. The embolic skin reactions (rose spots, p. 444) appear upon the trunk and extremities early in the disease. They are small erythematous macules about 2 to 5 mm. in diameter which may appear in successive crops and occur less frequently than in adults. A considerable degree of fatigue and emaciation often develops during the course of infection. The blood reveals evidence of a secondary anemia. There is a definite leukopenia, with disappearance of eosinophils and a relative increase in the number of mononuclear cells. Relapses occur in about 10 per cent of infections, but are usually less severe than those in the adult.

**In infants.** The infection may be present at birth, the organism having been transmitted through the placenta. In such instances the infant may be born prematurely and die soon after birth, though recovery is possible. The symptoms are variable and may include fever, convulsions, jaundice, diarrhea, and enlargement of the spleen. Diagnosis is established by isolating the organism from the blood or feces. A positive Widal reaction indicates infection of the mother and not necessarily active infection of the offspring.

When an infant acquires infection after birth, the clinical pattern may be far from typical. It may resemble that of sepsis or may suggest only a mild intestinal disturbance. Diarrhea, abdominal distention and vomiting are frequent, but there may be constipation. Distention may be related to low levels of potassium in the serum. The temperature is usually high and irregular, and rose spots are present in about half of the cases. The spleen is enlarged. An unexpected diagnosis is occasionally made from blood cultures in otherwise unexplained and atypical infections.

Because opportunity for contact with the typhoid bacillus is relatively limited during infancy, only about 1 per cent of all cases occur during the first year of life. The mortality rate of the disease among infants is about 10 per cent.

**Diagnosis.** Influenza, tuberculosis, malaria, undulant fever, atypical pneumonia, meningitis, rheumatic fever and other *Salmonella* infections are diseases that frequently

must be considered in the differential diagnosis. In the infant the clinical manifestations may resemble those of bacillary dysentery or septicemia. Obviously typhus fever must be considered in localities where both diseases exist.

Bacterial cultures of the blood, feces and urine should be obtained in every suspected case. The organism can almost always be isolated from the blood stream during the first week of the disease; the stool culture is usually positive, and in about one third of the cases the organism can be isolated from the urine. After the tenth day of illness the agglutination test (Widal) becomes positive in the majority of cases (see p. 388).

**Complications.** Complications, including hemorrhage and perforation of the bowel, are less frequent in children than in adults. Symptoms of *shock* accompany perforation of the intestine. The temperature falls abruptly, and the pulse rate increases. Abdominal pain is great, and distention usually develops. The abdominal muscles are rigid. With beginning *peritonitis* the fever reappears and leukocytosis occurs. Peritonitis may occur without evidence of perforation. *Intestinal hemorrhage* seldom occurs in patients under ten years of age. Extensive bleeding from the bowel is characterized by pallor, rapid pulse, fall in blood pressure and absence of abdominal pain. Bleeding from the mucous membranes associated with purpura (hemorrhagic typhoid) is rare. Epistaxis is the most common type of hemorrhage and may be severe. *Thrombosis* and *phlebitis* occur occasionally in children.

*Hepatitis*, of a degree sufficient to produce icterus, occurs occasionally. *Acute cholecystitis* and formation of gallstones are rare complications. *Infections of the respiratory tract*, particularly bronchitis, are frequent during the early stage of typhoid; bronchopneumonia may occur in the late stage. As in other *Salmonella* infections, there may be localized *arthritic*, *periosteal* and *osseous* infections, which are more likely to occur when the bacteremia is prolonged.

*Infection of the urinary tract* occurs in about one fourth of the cases. *Cutaneous* lesions include furuncles and bed sores which may be foci for staphylococcal or streptococcal septicemia. Sudamina, urticarial rashes, herpes, epilation, and grooving of the nails are other occasional epidermal manifestations.

*Nervous complications* are relatively com-

mon, and such symptoms as delirium, stupor and mental depression are frequent. There are rarely residual defects from toxic encephalitis; aphasia, a rare late manifestation, is usually only temporary. Chorea, hemiplegia, optic neuritis and peripheral neuritis have been reported. Purulent meningitis and brain abscess are rare and often fatal.

**The carrier.** During convalescence the patient often continues to harbor the causative agent and excrete it in the stools or urine. About two thirds of the patients are free of organisms by the end of six weeks. Most of the remaining third become free of organisms within a year, but about 3 per cent remain positive after a year and are considered chronic carriers. Adult chronic carriers are about nine times as frequent as child carriers, and females apparently outnumber males.

The nidus of the organism in the permanent carrier is usually in the gallbladder, occasionally in the intestine, kidney or a fistula.

The bacteriophage technique of typing typhoid bacilli is useful for tracing the role of the carrier in the spread of the disease. In addition, the finding of a high titer of serum antibody against the "Vi" antigen is almost entirely confined to the carrier state.

Surgical removal of the gallbladder in selected cases is an effective method of eliminating the chronic carrier state. The practical management of the carrier requires the closest cooperation of the carrier, his family and the health department.

**Prevention.** Sanitary living constitutes the most important preventive measure. In communities where this prevails, routine vaccination may not be necessary. When exposure has occurred or is probable, vaccination should be done. Although vaccine containing only typhoid bacilli is less irritating than the triple vaccine containing paratyphoid A and B organisms, the latter is preferable. For older children (five years and above) three weekly injections of 0.5 cc., 1 cc., and 1 cc., respectively, are sufficient. One half to one third of this dose may be given to children under five years of age. Single "booster" injections may be given every two or three years. There is evidence suggesting that 0.1 cc. of the vaccine injected intradermally is adequate for this purpose.

**Treatment.** Good nursing care and the maintenance of proper nutrition are important. In uncomplicated cases a high caloric,

smooth diet is desirable. A decrease in the fat content and the use of the more readily absorbable sugars are helpful in patients with tympanites or diarrhea. Lactose may be fed in larger amounts than other sugars because it is less sweet and is not fermented by the typhoid bacillus. Minerals and the various vitamins should be given in adequate amounts. The maintenance of fluid and electrolyte balance is especially important in infants and small children. There should be particular attention to the possibility of potassium deficiency when abdominal distention is associated with protracted vomiting or diarrhea.

Excessively high fever (105° F. or higher) may be treated by tepid sponge baths and alcohol rubs. Constipation may be controlled by the administration of mineral oil and by occasional enemas. Purges are contraindicated. In diarrhea a high-protein, low-fat diet should be prescribed. Lactic acid skimmed milk reinforced by the addition of a suitable protein mixture may be helpful. The feeding of scraped raw apple or an apple pectin preparation or the use of one of the hydroscopic agents such as pectin-agar may be beneficial in adding bulk to the stool and decreasing intestinal irritation. Opiates should not be used. Blood transfusions are indicated to correct anemia.

An antiserum, prepared according to the method of Felix, contains antibodies against the "Vi" and the "O" antigens; when injected early in the disease, it is said to be effective against the toxemia.

Chloramphenicol is the drug of choice for the treatment of typhoid fever. An initial dose of 50 mg. per kilogram (25 mg. per pound) is followed by a daily dose of 25 mg. per kilogram (12.5 mg. per pound) given in divided doses every six hours until the temperature is normal (usually about five days). Thereafter the daily dose is 3 mg. per kilogram of body weight for a total of ten to fourteen days. These are relatively small doses; in some clinics 50 to 100 mg. per kilogram of body weight in divided doses are administered for the full period of ten to fourteen days. When oral medication is not feasible, the intravenous preparation of chloramphenicol may be used.

The patient should be carefully isolated and screened against contact with flies. The urine, sputum and feces should be treated with Lysol before being discarded. Three negative urine and stool cultures should be

FIG. 121. Showing the curative effect of chloramphenicol in typhoid fever. D.A., 3 years of age, became ill 24 hours before admission with anorexia, lethargy and a temperature of 103° F. A sibling, the mother and 2 neighbors also had the disease, contracted by drinking water from a nearby polluted stream. Note (a) the lag period between onset of treatment and fall of temperature; (b) the characteristic decrease in the percentage of granulocytes (P) as the effect of the drug is manifest, and the increase upon cessation of treatment.

obtained before the patient is released from isolation.

#### SALMONELLA INFECTIONS

These infections are caused by a number of flagellated organisms which have a common relationship based upon antigenic structure.

They are members of the *Salmonella* genus and have "H" (flagellar) and "O" (somatic) antigens, as does the typhoid bacillus, which some bacteriologists include as a member of the *Salmonella* group. A number of the *Salmonella* bacteria are natural pathogens for animals. The disturbances produced in man are, in general, of two types: a typhoid-like fever (paratyphoid fever) and acute gastroenteritis (food poisoning).

**Etiology.** Based upon antigenic studies, the *Salmonella* organisms are subdivided on the basis of their "O" antigen characteristics. Within each subgroup they are further differentiated on the basis of their "H" components; of the more than 150 identified species, some of the more common ones are:

- Group A: *S. paratyphi* (paratyphoid A bacillus)
- Group B: *S. schottmuelleri* (paratyphoid B bacillus)
- S. typhimurium* (*Bacterium aertrycke*)
- Group C<sub>1</sub>: *S. hirschfeldii* (*S. paratyphi* C.)
- S. choleraesuis* (*Bacterium suispestifer*)
- S. oranienburg*
- S. montevideo*
- Group C<sub>2</sub>: *S. newport*
- Group D: *S. typhosa* (typhoid bacillus)
- S. enteritidis* (*Bacterium enteritidis*)

*S. gallinarum**S. pullorum*Group E: *S. anatis* (*Bacterium anatum*)

Those organisms which are primarily human pathogens and usually cause typhoid-like infections are *S. typhosa*, *S. paratyphi*, *S. schottmuelleri* and *S. hirschfeldii*. Those which are primarily pathogenic for animals or birds, but occasionally cause human infection, chiefly through contaminated foods, are *S. typhimurium*, *S. choleraesuis*, *S. oranienburg*, *S. montevideo*, *S. newport*, *S. enteritidis* and *S. anatis*. *Salmonella gallinarum* and *S. pullorum* are also occasionally responsible for gastroenteritis through contamination of food. Certain species, notably *S. hirschfeldii* and *S. choleraesuis*, frequently invade the blood stream and produce localized purulent lesions such as osteomyelitis.

**Epidemiology.** In general, members of the *Salmonella* group of organisms have two common characteristics: (1) most of them (*S. paratyphi*, *S. schottmuelleri* and *S. hirschfeldii* are exceptions) have a natural habitat in animals, and (2) they remain viable for considerable periods of time and multiply in contaminated food. Rats, mice and hogs and other animals, such as fowls, rabbits, cats, dogs, cows and horses, may act as natural reservoirs. Meat, eggs, vegetables, milk and water are often contaminated, especially at warm temperatures, by food handlers, flies or the droppings of infected rodents. Packaged foods such as powdered egg can be responsible for wide dissemination. Man usually becomes infected by eating contaminated food, but also probably acquires infection by handling animals. Convalescent patients, especially infants, may be infectious for long periods of time. There are permanent carriers for *S. paratyphi* A and B, as well as for some of the other types.

Epidemics of paratyphoid and typhoid fever may coexist, and both infections may even occur simultaneously in the same patient. Standard typhoid vaccines contain paratyphoid A and B bacilli, and it may become practicable to include other organisms of the *Salmonella* group.

**Pathology.** Tissue changes are similar to, though less marked than, those encountered in typhoid fever. Acute enteritis and superficial necrosis of the lymphoid tissue are the principal changes in the intestinal tract. Deep ulceration and frank hemorrhage are rare, and perforation of the bowel in children is practically unknown.

**Clinical Manifestations.** The clinical manifestations may be extremely variable, though the predominating symptoms are usually gastroenteric, pulmonic or septic. Two general clinical types may be recognized: (1) the typhoid-like type (paratyphoid fever) and (2) the food-poisoning type (gastroenteritis). *Salmonella paratyphi* A, *S. paratyphi* B and *S. paratyphi* C usually produce symptoms resembling those of typhoid fever, while *S. typhimurium*, *S. enteritidis* and *S. choleraesuis* more often cause the food-poisoning type. However, either type of illness may be caused by any of the *Salmonella* organisms.

The incubation period may be as brief as a few hours in the food-poisoning type or as long as twelve days in typhoid-like infections. Headache, nausea and vomiting are initial symptoms. Abdominal pain and diarrhea are common in both types and constantly present in the food-poisoning type. The stools may be watery and at times contain mucus and blood, suggestive of dysentery.

There may be considerable drowsiness, and in some instances the sensorium is disturbed. Meningismus is often marked, and in such instances the possibility of meningitis cannot be eliminated without a diagnostic lumbar puncture. In paratyphoid A, B and C infections, rose spots (Fig. 122) may be present. The spleen is not regularly enlarged, but abdominal distention is not uncommon. There may be either leukopenia or leukocytosis, the former occurring more often in paratyphoid B infections, the latter in *S. typhimurium* and *S. enteritidis* infections.

Suppurative lesions of the joints, bones and soft tissues are more common than in typhoid fever, and are particularly characteristic of infection with the members of group C, of which *S. hirschfeldii* and *S. choleraesuis* are the principal ones. Meningitis is an occasional complication and has a high fatality rate.

The duration of the disease, though variable, is shorter than that of typhoid fever. The temperature may remain at a moderately elevated level throughout or may be of the septic type. When death occurs, it usually follows a course of illness in which there have been extreme dehydration, toxemia and circulatory collapse.

**Diagnosis.** Typhoid fever, bacillary dysentery, meningitis, osteomyelitis, acute appendicitis and staphylococcal and streptococcal food poisoning are among the more important conditions likely to be confused with *Salmonella* infections.

FIG. 122. Rose spots in paratyphoid fever in male, 17 months of age. Duration of fever, 15 days. Exanthem appeared on fourth day. Blood culture positive (fourth day) for *S. paratyphi* B. Serum agglutination, seventh day, negative; eleventh day, 1:640 vs. *S. paratyphi* B; stool culture, seventh day, positive, *S. paratyphi* B. (Courtesy of Dr. Kenneth Landauer.)

The bacteriologic diagnosis consists in (1) isolation of the organism from the blood, stools, urine or pus from a suppurative lesion; and (2) demonstration of a significant agglutinating titer of the patient's serum. Identification of an organism as a member of the *Salmonella* group is dependent upon serologic typing. Cross agglutination reactions frequently occur because of the close antigenic relationships among the *Salmonella* organisms. In instances in which contaminated food is suspected, it should be cultured.

**Complications.** The most common complications are those due to septic localization of the organism and include arthritis, osteomyelitis, meningitis and abscess of the soft tissues. Intestinal perforation is extremely rare. Bronchitis is frequently present in the early stage, as in typhoid fever, and is often mistakenly considered to be the cause of the fever. Bronchopneumonia may be a later complication.

**Prognosis.** The case fatality rate, though not accurately known, is less than that of typhoid fever; in certain epidemics, rates of 5 to 10 per cent have occurred, but the general mortality rate is considerably lower. The mortality rate appears to be higher in the paratyphoid group of infections than in cases of acute food poisoning.

**Treatment.** The patient should be isolated, and precautions similar to those recommended for typhoid patients should be practiced. When diarrhea and vomiting are

excessive, it may be necessary temporarily to discontinue feeding by mouth. Adequate fluid administration is necessary. (See p. 187 for treatment of diarrheal states.) Suppurative joints require surgical incision and drainage.

Drug therapy in salmonellosis is difficult to evaluate, since the course of the natural disease is extremely variable. Bacteriologically, some of the antibiotics appear to be effective in the acute phase; but upon cessation of treatment, positive cultures frequently re-occur. By then, however, the general condition of the patient is improved, and a certain degree of immunity established. Chloramphenicol (not so effective against other types as against *S. typhosa*) and Terramycin appear to be the drugs of choice; the latter has been reported to be effective, especially against *S. choleraesuis*. Aureomycin is less effective, the sulfonamides are equivocal, and streptomycin is of little or no value.

In the carrier state the choice of an antibiotic should be based upon sensitivity tests.

## BRUCELLOSIS

(UNDULANT FEVER, MALTA FEVER, BANG'S DISEASE)

Brucellosis is an infectious disease which primarily affects domestic animals, but is transmissible to man, in whom it produces a variety of clinical patterns. Infection in children is less frequent than in adults.

**Etiology.** There are several strains of *Brucella* organisms, classified as follows: *B. melitensis* (goat), *B. abortus* (cattle) and *B. suis* (swine). These species may be differentiated by the dye-typing method of Huddleson. They may be further identified by their ability to produce hydrogen sulfide.

**Epidemiology.** Human infection occurs where the disease is prevalent among domestic animals. Therefore it is more frequent in rural areas and among farmers, veterinarians and slaughterhouse workers in intimate contact with infected animals. About 10 per cent of the cattle and 3 per cent of swine in the United States are infected.

The disease is worldwide and occurs in all climates. It is four times more frequent in males than in females and is relatively infrequent among infants and children (see Table 69).

Ingestion of raw milk and its products accounts for about one fourth of the cases, the remainder originating from contact with infected animals or their environment (Spink). The skin and conjunctivas are important portals of entry, and inhalation of *Brucella*-contaminated dust is a probable method of infection. The laboratory is an occasional source of infection.

**The disease in children.** Children are considered less susceptible than adults. The apparent relative immunity of the young is not fully understood. McBride states that among forty-eight children who ingested contaminated milk, nine developed agglutinins, and only two exhibited clinical manifestations of the disease. Obviously, children have less opportunity for direct contact with infected animals. In general, the infection in children is less severe than in older subjects. Intra-uterine infection has been reported, and *Brucella* organisms have been demonstrated in the colostrum of an infected mother.

**Pathology.** The pathologic changes are nonspecific and appear to involve principally the reticuloendothelial system. Histologically,

there is hyperplasia of the reticuloendothelial system, and granulomatous foci and focal necroses in the liver, spleen, and lymph nodes.

**Clinical Manifestations.** The incubation period varies between five and thirty days, but is usually about two weeks.

**Acute form.** The onset of the acute form is often gradual, with fatigue, irritability, headache and malaise which may exist for several days or weeks before fever occurs. Pain in the chest with a nonproductive cough may be observed. In other instances the onset is sudden with fever, chills and nocturnal sweating. The onset may resemble that of mild typhoid fever. Frequently the patient feels well in the morning, but quite ill in the afternoon. This alternating daily cycle of well-being and extreme malaise eventually leads to weakness, loss of weight, and secondary anemia. Anorexia, constipation and abdominal pain are frequent complaints, and diarrhea and bloody stools occasional ones. The course may persist for several months. The febrile episodes are often intermittent, with fever, lasting from one to two weeks, followed by afebrile periods.

The wide variety of localized manifestations of brucellosis and the relative infrequency of the infection in infants and children make it impossible to define a characteristic pattern except for the undulating fever, weakness and the possibility of localization in most organs and tissues. The liver and spleen may become enlarged and tender, and occasionally jaundice occurs. Lymph node involvement may be widespread, and there may be abscesses in them as well as in the subcutaneous tissue. Bone and joint involvement is relatively common; the large joints and the spine are more frequent sites of infection. Ocular manifestations include

From the Laboratories of the Minnesota State Department of Health.

\*Calculated from data by W. W. Spink, in Brennemann-McQuarrie: Practice of Pediatrics. Hagerstown, Md., W. F. Prior Co., Inc., 1957, Vol. 2, Chap. 33, p. 4.

keratitis, retinitis, uveitis, papilledema and optic neuritis. Purulent meningitis and infections of the urinary tract are occasional manifestations. At times skin lesions resembling rose spots occur.

There is usually a leukopenia with a relative lymphocytosis, although the total leukocyte count is frequently normal and at times increased. An increase in the number of large mononuclear cells and eosinophils may also be observed. The clotting time may be prolonged, with imperfect clot retraction. Secondary anemia is common.

**Chronic form.** Chronic brucellosis presents a variety of symptoms. In older children and adults they may be so vague as to suggest neurasthenia. Generalized weakness, prolonged malaise, low grade fever, insomnia and vague aches and pains are common. The undulating type of fever frequently observed in the acute form is seldom seen in chronic brucellosis. Bursitis, peri-arthritis and spondylitis should suggest the chronic form of infection. Persistent and intermittent lymphadenitis may be observed. In young children there may be no characteristic symptoms.

**Diagnosis.** A history of unexplained fever in a patient who has ingested raw milk products is suggestive of brucellosis. The disorders that may resemble brucellosis include typhoid fever and other *Salmonella* infections, malaria, tuberculosis, Hodgkin's disease, rheumatic fever, influenza, tularemia, arthritis, appendicitis, cholecystitis, subacute bacterial endocarditis and even neurasthenia.

The diagnosis is established by identification of the organism in the blood, urine, bile, joint fluid, aspirates from abscesses or biopsy material. Cultures should be observed for two or three weeks.

Agglutinins may appear in the blood by the tenth day of the disease, or not until late in convalescence; in 5 to 10 per cent of active infections in man they may not be demonstrable at any time. On the other hand, agglutinins may be present in the blood serum of certain persons who have consumed raw milk, but are free from symptoms, and in those who have had intradermal tests with *Brucella* antigens. Though a titer of 1:80 to 1:160 is generally considered significant, dependence cannot be placed on a particular titer because of lack of a standardized antigen. However, the demonstration of a rising titer is of diagnostic significance. Falsely positive agglutinative titers may appear in

tularemia and in persons immunized with cholera vaccine.

The complement fixation is as useful as the agglutination reaction. The complex phagocytic index is of little practical value. Guinea pigs may be injected subcutaneously with suspected infectious material and their serum subsequently tested for agglutinins, and their tissues may be examined for lesions of brucellosis.

A positive intradermal reaction may be obtained in the majority of active human infections by injection of a suspension of heat-killed organisms or the nucleoprotein of the organism (brucellin). The reaction is an allergic one resulting from past or present infection; it is useful for epidemiologic surveys, but has limited value as a diagnostic aid. The combination of nonspecific symptoms and a positive skin reaction is insufficient for a diagnosis of brucellosis.

**Complications.** In a disease whose natural course may be as prolonged as that of brucellosis and whose manifestations are as protean, it becomes somewhat arbitrary to designate particular lesions as chronic manifestations or as complications. In any event, arthritis with or without hydroarthrosis, osteomyelitis (especially spondylitis), pericarditis, peritonitis, pleurisy, meningitis, encephalitis, infection of the urinary tract, abscesses of the lymph nodes and subcutaneous tissues and purpura have all been observed in cases of long standing. Endocarditis of the vegetative type may result from *Brucella* infection superimposed on a previously damaged heart valve.

**Prognosis.** Death occurs in about 1 per cent of recognized cases. The prolonged disability, often lasting for months or years, is the important feature. In children the disease is less severe than in adults. Relapses are more frequent in persons in whom a definite increase of humoral antibodies (agglutinins) fails to develop, and in those with mild symptoms.

**Prevention.** Isolation of the patient is unnecessary, since human transmission seldom, if ever, occurs. Caution, however, should be exercised in handling infected tissues or exudates. The infection may possibly be transmitted by blood transfusions.

The prevention of brucellosis consists in (1) pasteurization of milk and its products; (2) eradication of the infection in domestic animals; (3) vaccination of persons intimately associated with diseased animals or who have laboratory contact with the organ-

ism; and (4) public education concerning the danger of consuming raw milk.

**Treatment.** The first successful therapy was accomplished with streptomycin and sulfadiazine. Later it was found that one of the broad-spectrum antibiotics or a combination of one of them with streptomycin was more effective, especially in reducing the incidence of relapses. Spink recommends Aureomycin (other tetracyclines are also effective) alone for the milder infections caused by *Br. abortus*. For the more severe *Br. abortus* infection and for all infections due to *Br. suis* or *Br. melitensis* he suggests a combination of Aureomycin with dihydrostreptomycin.

The Aureomycin is given orally four times daily for three weeks, and the dihydrostreptomycin intramuscularly twice daily for at least two weeks.

Corticotropin and cortisone appear to be of benefit in controlling the acute manifestations, but should be given only to the acutely ill patient with toxemia.

Desensitization by injection of a *Brucella* antigen has been used, particularly in the chronic type of the disease, but is inferior to antibiotic therapy.

Rest and psychotherapy are important adjuvants in the management of the chronic case.

## TULAREMIA

(RABBIT FEVER)

Tularemia is an infectious disease of rodents which is transmissible to man.

**History.** Tularemia was identified in Tulare County, California, in 1910 by McCoy, who observed a "plaque-like disease" among ground squirrels. Wherry (1914) described the first case in a human being. Francis (1920) produced the disease

in the guinea pig by inoculating it with the blood of a person who had died after the bite of a deerfly.

**Etiology.** *Pasteurella tularensis* is a small, gram-negative, coccoid bacillus, 0.3 to 0.7 micron in length. It is probably nonmotile, though Ohara described it as slightly motile. It forms capsules and is easily destroyed by the usual disinfectants and by heating at 56° C. for ten minutes.

**Epidemiology.** In the United States important sources of infection are animals, insects and laboratory material. Over 90 per cent of human cases in the United States have occurred after contact with infected wild rabbits. Birds (quails, chickens) and cold-blooded animals may also harbor the organism. Various insects serve as vectors; these include the woodtick, dogtick, horsefly, bedbug, flea, louse; in Utah the deerfly plays an important role. The seasonal incidence is influenced by the period of the year when ticks are prevalent or when rabbits or other game animals are being hunted or trapped.

Tularemia is widely distributed. It has been observed throughout the United States, Alaska and Canada, in Japan, where it is known as "Ohara's disease," and in Norway, Russia and other parts of Europe. The disease is more frequent among adults than among children.

Infection may be acquired by skinning or dressing of rabbits and such other animals as skunks, deer, foxes, rats and tree squirrels; it has followed the bites of such animals as dogs, cats, squirrels and raccoons. Contact with sheep may result in infection, especially among shearers, since the wool may contain infected ticks and contaminated fecal droplets. Infection may also be acquired by ingestion of inadequately cooked contaminated meat or the drinking of contaminated water; the organism has been demonstrated in the water of several streams. Transmission from man to man, though possible, is not probable. Laboratory infection is common; unless extreme care is exercised, practically everyone who handles fluid cultures or infected animals contracts the disease. One attack of the disease usually confers lasting immunity.

**Pathology.** In addition to the local lesion at the portal of entry and the lesions in the regional lymph nodes, there are focal necrotic areas in various stages of evolution throughout the body. Small yellow-white lesions are found in the spleen, liver, kidneys, lungs, lymph nodes and bone marrow. Histologically, the lesions may resemble miliary tuber-

cles with or without central purulent exudate. In the central areas of these lesions polymorphonuclear cells are abundant, often associated with central necrosis and surrounded by an area of small round cell infiltration. In the more diffuse lesions, fibroblasts and mononuclear cells are abundant, particularly during the subacute stage of the infection.

**Clinical Manifestations.** The average incubation period is three to five days. Based somewhat upon the reaction at the portal of entry, six clinical types are generally recognized: (1) ulceroglandular, (2) oculoglandular, (3) glandular, (4) pulmonary, (5) typhoidal and gastrointestinal, and (6) oropharyngeal. Manifestations are both local and generalized.

The onset is abrupt, with fever, chills, headache and vomiting. Generalized pains, prostration and sweating are usually present. Sometimes there is enlargement of the liver and spleen. Various exanthems (macules, papules, pustules and petechiae) may be observed as well as jaundice. Fever lasts one to two weeks.

The local lesion, a papule, usually becomes ulcerated with enlargement and tenderness of the regional lymph nodes, which suppurate in about half of the cases.

When the portal of entry is the conjunctiva, photophobia, itching, lacrimation, hyperemia and swelling of the eyelid, usually the upper, occur. Preauricular and cervical lymph nodes enlarge and frequently suppurate. Though damage to the eye is rare, corneal ulcers may sometimes perforate and permanently impair vision.

The *pulmonary* type occurs from inhalation or by the hematogenous route. The pneumonia is patchy, confluent and often migratory. The mediastinal and peribronchial lymph nodes are enlarged.

The *oropharyngeal* type, resulting from ingestion of contaminated material, is characterized by ulcerated lesions of the oral cavity, throat and tonsils with cervical adenitis. The tonsils may be covered with exudate or a pseudomembrane, not unlike that of diphtheria. Several members of the family may be infected from a common source of food or water. Hughes and Etteldorf observed fifty-five proved cases of tularemia in Memphis (1940-56); thirteen of the patients were under sixteen years of age, and five of the thirteen cases were of the oropharyngeal type. In children this type may be rapidly fatal.

Cryptogenic infection may occur, and the

clinical course may resemble that of typhoid fever.

There is moderate leukocytosis and secondary anemia. Albuminuria is common.

**Diagnosis.** The disease may resemble atypical pneumonia, psittacosis, undulant fever, septicemia, influenza, tuberculosis and the typhoid-paratyphoid group of diseases. The typical case in which the patient becomes ill after dressing or skinning a wild rabbit should offer little difficulty in diagnosis.

Confirmation may be obtained from agglutination and skin tests and from bacterial cultures and inoculation of laboratory animals. By the end of the second week of illness the patient's serum contains specific antibodies, and the agglutinin titer gradually increases, sometimes exceeding 1:1280. The skin test, described by Foshay, consists in the intracutaneous injection of a suspension of detoxified formalin-killed *P. tularensis*. The tuberculin-like reaction is said to occur by the third day of illness.

**Complications.** Chronic bronchitis, bronchopneumonia and pleural effusions are probably more common than clinical symptoms suggest. Peritonitis, sometimes with persistent ascites, may develop. Pericarditis, thrombophlebitis, osteomyelitis, purulent meningitis and encephalitis have been described.

**Prognosis.** The case fatality rate is about 5 per cent. The pulmonary and the gastrointestinal types of the disease are extremely serious, often resulting in mortality rates as high as 60 per cent. The course of the disease is variable. Many patients are only mildly ill; in others there is extreme toxemia. The fever usually lasts three to four weeks, but the glandular enlargement may last three to four months, and convalescence may be prolonged even longer. Because *P. tularensis* is frequently an intracellular organism, it may remain viable in the tissues long after symptoms have disappeared.

**Prevention.** Prevention largely involves avoiding contact with infected rodents or other animals and with ticks and insect vectors. Face masks and rubber gloves should be worn by those handling infectious material in the laboratory. Proper cooking will eliminate rabbit meat as a source of ingestional infection. Prophylactic vaccination of animals or man has not proved practicable.

**Treatment.** *Pasteurella tularensis* is sensitive in vitro to 0.15 to 0.3 microgram per cubic centimeter of streptomycin. Streptomycin in doses of 25 mg. per pound of body weight per day in divided doses every six

hours is usually responsible for rapid recovery; treatment is usually continued for one week. Aureomycin is also effective, but does not excel streptomycin. Experience with other antibiotics has not been extensive.

Symptomatic care is important. The discharges from open lesions should be handled so as to prevent spread of infection. Surgical incision of suppurative lesions is frequently followed by systemic reactions.

## TUBERCULOSIS

Tuberculosis has a uniquely important place in man's medical history. It has at all times been a major cause of illness and of death in all climates. It was one of the first diseases to elicit widespread organized public health efforts, and the degree of control attained has proved the value of detection and isolation of infected persons. It stands as the prototype of infections which exist in man most often as a parasite without causing significant disease and yet capable of producing both acute and chronic disease patterns of sufficient seriousness to be a major cause of death.

The steady decrease in death rates at all ages (Fig. 123) is evidence of man's gain in his battle with the tubercle bacillus. Only in the last decade can credit for these gains be given to specific antimicrobial agents. It is essential for the young student to know by what means these gains have been made and to recognize that in our improving health situation, tuberculosis remains a major problem—to be solved by the combined means of public health measures and medical therapy.

**Etiology.** Koch demonstrated in 1882 that tuberculosis is caused by the acid-fast bacillus *Mycobacterium tuberculosis*. Subsequently Theobald Smith showed that disease in man could be produced by bovine and human

tubercle bacilli. The bacilli are capable of living and remaining virulent for weeks in a dry state, but in a fluid suspension are killed by a temperature of 60° C. (140° F.) within fifteen or twenty minutes.

The tubercle bacillus does not contain or produce any chemical constituent which has any measurable toxicity for tissues not sensitized to tuberculin; its tissue-necrotizing capacity exists in the protein fraction. The lipids of the tubercle bacillus give it the property of acid-fastness and appear to be a factor in the production of fibrosis as well as in the formation of epithelioid cells and tubercles.

**Epidemiology.** The exact incidence of tuberculosis is not known. Evidence of its frequency is limited to surveys using the tuberculin test and/or roentgenographic films, clinical recognition of the disease, and examination of autopsy material. Available data indicate that the incidence of infection is declining throughout the world and that in general the incidence is lowest in populations with high living standards, and highest in those with low standards. In all areas the incidence of tuberculous infection increases with age and is generally higher in urban than in rural areas. Some idea of the decrease in the rate of infection may be obtained from the decrease in rates of positive tuberculin reactions. Whereas rates of positive reactors were 50 to 90 per cent during high school and college ages twenty to thirty years ago, rates of positive reactions in this same age group at present are only 5 to 20 per cent. Figure 123 illustrates the decrease in mortality during this century, and Figure 124 illustrates the differences in mortality rates by age, sex and race.

Infection rates among children are higher in tuberculous families than in nontuberculous ones. Infection of children below the age of five years is most likely to occur at home from members of the family or domestic servants; infection of older children is more likely to be acquired from contacts outside the home. The relatively high incidence of tuberculosis in persons beyond fifty years of age necessitates the inclusion of *all* contacts irrespective of age (*viz.*, grandparents) as possible sources of infection.

Inspection of death rates (Fig. 123) reveals that there has been a progressive decrease in all age groups since 1900. This drop is especially marked in the groups under fifteen years of age. Although the death rate in infancy and early childhood (Fig. 124) is higher than in the age group of five to fifteen

FIG. 123. Tuberculosis death rate by age, United States, 1900-1955 (expanding death registrations). (Tuberculosis Program Charts, 1957, XVII.)

FIG. 124. Age-specific tuberculosis death rates by race and sex, United States, 1955. (Tuberculosis Program Charts, 1957, XVIII.)

years, the difference is much less than was the case in the past. The relatively high mortality rates of infancy and adolescence characteristic of previous years have now been greatly reduced.

**Predisposing Factors.** The introduction of tubercle bacilli into the human body is not invariably followed by the development of significant disease. Pertinent to an understanding of this situation is why certain persons have greater resistance to infection than do others, and why the resistance of a given person may vary from time to time.

Factors related to the tubercle bacillus which may affect the establishment of disease in a given structure of the body (see Pathogenesis) are principally of two orders: the relative virulence of the invading organisms and the number of organisms in the inoculum. Though there are distinct differences in the virulence of various strains of tubercle bacilli, strains of low virulence are rarely encountered in human infections.

**Heredity.** There is no evidence of an inherited tendency to tuberculous infection. Differences in constitutional patterns do

however, appear to influence resistance to disease. Animals of the same species vary in their degree of resistance, and by selective breeding of those with a high degree the increased capacity for resistance can be transferred to the offspring. The question in man is not so simply answered. It has been suggested that persons with a low resistance account for the majority of those who have progressive tuberculosis, and that the decrease in mortality from tuberculosis is at least in part attributable to the law of the survival of the fittest.

**Congenital or intrauterine infections** occur infrequently; infection of the fetus is probably secondary to infection of the placenta.

**Race.** Differences in racial immunity are not well defined. There is a higher mortality rate from tuberculosis in the United States among the nonwhite population than among the white, but it would seem that much of this difference may be attributed to hygienic and environmental factors, such as poor housing conditions and opportunities for frequent reinfection from ambulatory patients.

**Age.** Age is a factor in resistance to tuberculous infection, the fatality rate being higher during infancy and adolescence than in the intervening years of childhood. There are also differences in the nature of the lesion which is initiated at various age levels. These are described under Pathology.

**Sex.** Sex appears to be a factor only in the latter part of childhood and during adolescence, when the incidence of tuberculosis and the fatality rate from it are higher in girls than in boys.

**Temporary factors affecting resistance.** Chronic illness and undernutrition may increase susceptibility to infection, as may a chronic state of fatigue. Acute nontuberculous infections may activate a quiescent tuberculous lesion.

**Allergy and Immunity.** Two to ten weeks after infection of a previously tuberculin-negative person with tubercle bacilli the presence of allergy can be demonstrated by a positive cutaneous reaction to tuberculin. With the development of allergy there is an alteration in the host response to tubercle bacilli, evidenced by exudation and a tendency to localize the infection. At some less well-defined time certain immune reactions also develop which are neither complete nor as adequately measured as in certain other infections. Immunity is not complete; it may be sufficient to protect against moderate infections, but may not be effective against

large numbers of invading bacilli or against those of exceptionally high virulence.

To what extent allergy and immunity are related phenomena is a controversial question. It is variously held (1) that they are related and perhaps identical, (2) that they are entirely separate phenomena, or (3) that they are opposing forces. It may be that the degree of hypersensitivity is the important factor. Thus moderate degrees of hypersensitivity appear to be effective in localizing the lesion and in bringing the phagocytic cells in contact with the bacteria more quickly; whereas greater hypersensitivity is responsible for such extensive destruction of tissue that spread of the infection may be increased by it.

**Pathogenesis.** Infection through the intact skin probably does not occur, but infections may be acquired in open wounds and through inapparent abrasions and have been transmitted by a human bite. Direct blood stream infection is a practical possibility only in placental transmission. Inhalation and, to a lesser extent, ingestion are the principal means by which tubercle bacilli gain entrance to the body and produce infection.

**Pathology.** The response of infants and small children to tuberculous infection differs in certain respects from that of older children and adults. There is, however, a good deal of overlapping between the responses of the two age groups. Thus lesions which have the characteristics of the "childhood type" are seen on occasion in adults, especially of the Negro race, and the "adult type" of infection may occur in children, especially in the latter part of childhood.

In general, the age differences are as follows: (1) The pulmonary lesion in infants and children may be in any part of the lung, but shows some tendency to be localized in the periphery. The site is more likely to be in the lower part of the lungs than in the upper part. By contrast, in adolescents and adults there is a predilection for localization of the lesion in the upper part of the lung, either in the apical region or just below it in the infraclavicular area. (2) The regional lymph nodes are more often involved in infants and children than in adolescents and adults. Initial infections in adults, except in the Negro, show little or no evidence of extensive involvement of the lymph nodes. (3) Both the parenchymal and nodal lesions in children exhibit a strong tendency to heal by calcification, whereas in adults the tendency is to heal by fibrosis. (4) Hematogenous dissemination is much more likely to occur

FIG. 125. Tuberculous lesion (primary) in apex of left upper lobe (right upper corner) with associated massive involvement of regional lymph nodes (primary complex). Large wedge-shaped lesion in lower half (lateral portion) of left upper lobe. This last lesion (tuberculosis pneumonitis) is secondary to bronchial erosion from a tuberculous node. (Courtesy of Drs. Charles Dunlap and James B. Arey.)

in infants than in older children. Miliary tuberculosis and tuberculous meningitis occur with much greater frequency in the first few years of life than they do subsequently.

At the site of the initial focus, as, for example, in the parenchyma of the lung, there is at first an accumulation of polymorphonuclear leukocytes. This reaction is temporary and is followed by proliferation of epithelioid cells which surround the tubercle bacilli, creating the typical tubercle formation. The tubercles are usually surrounded by an accumulation of lymphocytes, and giant cells are usually present. The tubercles may remain discrete or may become confluent; central caseous necrosis is commonly present. Individual foci of the primary infection vary considerably in size, but the majority apparently remain small (1 cm. or so in diameter). There is, as a rule, only a single primary focus, but there may be more.

Lymph node involvement is almost a constant accompaniment of the initial parenchymal lesion in children. It has generally been considered that lymph node involvement is a characteristic of the initial lesion of tuberculosis and does not occur in association with the lesion of reinfection. This concept does not appear to be wholly correct. There is evidence suggesting that the extent of involvement of regional lymph nodes is determined in part by age factors, being less with increasing age. The nodes become enlarged, often matted together, and tend to

adhere to adjacent structures. In the mediastinum they may exert pressure on the trachea, bronchi or blood vessels, and at times rupture into them. Softening and liquefaction of the nodes may parallel that in the primary focus or may occur independently. Auerbach believes that hematogenous distribution is more likely to occur from drainage from caseous foci in lymph nodes through lymph vessels into the venous circulation than by direct erosion into a blood vessel.

The tendency of the primary lesions both in the parenchyma and in the lymph nodes is toward healing in the majority of instances. There are, however, three mechanisms by which the primary infection may be responsible for serious damage during its active phase: (1) progressive destruction at its initial site; (2) erosion of a bronchus with intra-bronchial dissemination and the formation of other pulmonary lesions; and (3) hematogenous distribution resulting in one or more isolated foci in such parts of the body as the lungs, bones, kidneys, liver or brain, or in widespread miliary lesions involving some or all of the viscera.

The progressive primary tuberculous focus is a large, irregularly demarcated area of caseation with no definite capsule. The tissue surrounding this area tends to be pneumonic and the overlying pleura to be thickened. Softening and liquefaction may be generalized in the nodular mass or localized in one or more small areas. If the liquefied material is evacuated, there remains an irregular, shaggy excavation with a poorly defined capsule. Hematogenous distribution is more likely to occur during the stage of softening, but before the stage of liquefaction, whereas bronchogenic spread tends to result from the breakdown of an area of liquefaction.

Consolidated lesions in association with primary infections are usually atelectasis or tuberculous pneumonia, or a combination of the two. Bronchi may be occluded by external pressure from a caseous lymph node, or there may be erosion of the bronchus and occlusion of the lumen by the resultant intra-bronchial lesion. When the obstruction is incomplete, there may be greater hindrance to the exit of respired air than to its entrance, so that there is obstructive emphysema distal to the lesion; when the obstruction is complete, resorption atelectasis occurs.

Massive hematogenous dissemination of tubercle bacilli from a tuberculous focus results in widespread formation of tubercles. Though the heaviest distribution is likely to

be in the lungs, any or all of the viscera may be involved, especially the liver, spleen and kidneys. Tuberculous meningitis, as shown by Rich and McCordock, is more likely to result from breakdown of a tuberculoma situated in contiguity with the meninges. Isolated hematogenous lesions may be located in the brain, kidneys and bones and occasionally in other structures.

**Clinical Forms.** Tuberculosis may involve practically any organ or tissue of the body. Exogenous foci are naturally limited to structures which have an epithelial covering or lining, whereas tuberculosis of structures of the body which have no outside contact are of necessity blood-borne or lymph-borne from a pre-existing focus. Symptoms of any tuberculous lesion may be varied and may simulate many other disease entities. In the differential diagnosis of the majority of chronic infections and of many acute ones, the possibility of tuberculosis must be considered.

Intrathoracic tuberculous infection is the most frequent clinical manifestation of tuberculosis observed in this country and accounts for at least 90 per cent of recognized tuberculous disease in children. As noted under Pathology (p. 451), parenchymal and lymph node involvement uniformly occur, although these foci are not always apparent by clinical and/or roentgenographic examina-

tion. The extent of the infection in the pulmonary parenchyma and/or in the lymph nodes is largely responsible for the various clinical patterns. Table 70 provides a classification of intrathoracic lesions based on clinical patterns rather than the more traditional one of primary and reinfection tuberculosis. Extrathoracic tuberculous lesions are tabulated in Table 72 (p. 466).

#### INTRATHORACIC TUBERCULOSIS

**Clinical Manifestations.** The initial lesion in the lung may be, and usually is, a small localized one of 2 or 3 cm. From this lesion tubercle bacilli travel to and colonize in the regional lymph nodes. The two lesions constitute the so-called primary complex. The various possibilities for (1) healing, (2) persistence of indolent lesions, (3) extension at the local site with progressive destruction of tissue, (4) erosion of bronchial walls with partial or complete occlusion of the bronchial lumen (or such occlusions by external pressure of enlarged lymph nodes) with establishment of localized obstructive emphysema or atelectasis and at times with distribution of tubercle bacilli to other parts of the lung and establishment of a number of new lesions, (5) erosion of blood vessels with widespread distribution of tubercle bacilli (miliary tuberculosis) or with establishment of localized lesions at distant sites (cerebral tuberculoma, meningitis, bones, kidney, and the like), (6) subsequent reactivity of the lesion, or (7) reinfection, endogenous or exogenous, are individually and collectively responsible for the great variety of clinical patterns.

*It should be obvious that detection of tuberculin sensitivity in an individual requires careful study (1) to localize, if possible, the site of the lesion or lesions; (2) to determine whether the disease is active, quiescent or healed; and (3) to detect any existing tuberculous contacts.*

When no lesion can be demonstrated in the child by physical examination or on a roentgenogram of the chest, and there is no evidence of active infection manifest by fever, increased sedimentation rate or abnormal blood cell counts, the child may be diagnosed as *hypersensitive to tuberculin without clinically demonstrable disease*. Specific treatment should be considered for such children under three or four years of age and for those of any age who are known to have become tuberculin-positive within recent months (see p. 464).

When there are one or more *calcified foci in the pulmonary parenchyma and/or calcified*

**Table 70. Classification of Intrathoracic Tuberculosis**

Hypersensitivity to tuberculin without clinically demonstrable disease
Calcified pulmonary focus and/or calcified lesions in the tracheobronchial lymph nodes associated with hypersensitivity to tuberculin
Noncalcified pulmonary focus
Extensive pulmonary infiltration
Tuberculosis of the tracheobronchial lymph nodes
Intraluminal and extraluminal bronchial lesions
Localized ulcerative or granulomatous endobronchial lesions
Extraluminal bronchial compression
Lesions distal to bronchial obstruction
Emphysema
Atelectasis
Tuberculous pneumonitis
Or any combination of above 3 lesions
Caseous bronchopneumonia
Bronchogenic or hematogenous
Hematogenous tuberculosis
Single or multiple pulmonary infiltrations (clinically indistinguishable from nonhematogenous lesions)
Miliary tuberculosis
Apical and infraclavicular lesions
Pleurisy
(See page 466 for Classification of Extrathoracic Tuberculosis)

FIG. 126. Calcified tuberculous focus (right arrow) and calcified tracheobronchial lymph node (left arrow) in a Negro girl 10 years of age.

*lesions in the tracheobronchial lymph nodes* (Fig. 126) in a child with a positive reaction to tuberculin and no reaction to histoplasmin or coccidioidin and no evidence of active disease, he may be considered to be in an inactive state of tuberculosis. Calcified foci, especially those located close to the hilum, can usually be distinguished roentgenographically from blood vessels; the latter tend to have a smooth circular or elliptical homogeneous density, whereas the former are usually irregular in outline and density. Such a situation suggests a healed state, but the child must be watched for the possibility of a subsequent "break-down." In all cases a careful search for and elimination of tuberculous contacts are mandatory. Similar calcified intrathoracic lesions may be the residuals of histoplasmosis or coccidioidomycosis.

**Demonstrable noncalcified lesions.** As indicated in the initial paragraph of this section and in Table 70, a variety of lesions exist and require diagnostic differentiation.

The *noncalcified small pulmonary focus* appears on the roentgenogram as a more or less circumscribed area, usually not more than 1 or 2 cm. in diameter. There may or may not be evidence of associated hilar node involvement, but in infants and children there is likely to be. As a rule the child is not ill with this type of lesion. In children in the adolescent years such lesions are often located in the apex of the lung or the infraclavicular area, and in such circumstances initial tuber-

culous lesions may simulate the so-called reinfection lesions of adults.

On occasion the initial lesion in the lung is not confined to a small focal area, but extends into the surrounding lung tissue. Such an *extensive pulmonary infiltration* is often termed "progressive primary tuberculosis" (Fig. 127). Clinically, there are no certain methods for determining whether such a lesion is the initial one or is an exogenous reinfection or one resulting from hematogenous or bronchogenic dissemination. When only one such lesion is demonstrable, it is more likely to be an initial lesion which has been progressive; the distinction is, of course, academic. Such lesions may involve several lobules or most of a lobe.

Though there may be symptoms, not infrequently extensive pulmonary lesions are detected roentgenographically in children who have no complaints and whose parents have not observed any unusual manifestations.

Physical findings vary considerably. There may or may not be impairment to percussion. Rales may or may not be present. Cavitation occasionally occurs but, because it is likely to be farther away from the chest wall than in apical lesions, it may be missed on physical examination and even on roentgenograms. Tubercle bacilli can frequently be found in the sputum or in lavaged gastric contents.

*Infection of the hilar lymph nodes* is an almost constant accompaniment of pulmonary tuberculosis in infants and children. Th

nodes on the side of the parenchymal lesion are the ones usually involved, but the contralateral ones may also be infected. Frequently the only manifestation of the primary infection is the involvement of the tracheobronchial nodes, the parenchymal lesion being so small that it is not demonstrable even on the roentgenogram. The infection in the lymph nodes goes through the same stages as that of the parenchymal lesion and, until calcification is complete, is attended by the same danger of local extension and hematogenous dissemination.

There are frequently no symptoms (see p. 460). Though a brassy, paroxysmal cough is often attributed to enlarged nodes, it occurs so infrequently that it can scarcely be considered characteristic. Enlargement of the nodes is rarely demonstrable by physical signs. Cyanosis, edema of the face and dilatation of the superficial veins have been observed in association with extremely enlarged nodes, owing to compression of the larger blood vessels. Paravertebral dullness is rarely demonstrable. A murmur audible over the upper part of the sternum when the head is thrown

FIG. 127. Extensive infiltrative lesion in the middle portion of the right lung in a white boy 20 months of age.

FIG. 128.

FIG. 129.

FIG. 128. Noncalcified tuberculous lymph node.

FIG. 129. Secondary hematogenous lesions in the third toe (dactylitis) of the same child. The films were taken on the same date.

FIG. 130. Tracheobronchial caseocalcareous lymphadenitis in an apparently healthy Negro boy, detected in a routine survey.

back (Eustace Smith's sign) can be heard whether or not there is an enlargement of the lymph nodes, and d'Espine's sign, a spoken or whispered pectoriloquy or an echo from the spoken voice heard below the level of the seventh cervical or first dorsal vertebra, is not discriminating.

Roentgenographic demonstration of enlarged nodes in conjunction with a positive tuberculin reaction constitutes the best evidence for diagnosis. When the lymph nodes are not large and merge into the other hilar structures, they may not be distinguishable. Calcification may be considered evidence in favor of a tuberculous etiology, when the tuberculin test is positive and the histoplasmin and coccidioidin tests are negative.

*Intraluminal and extraluminal bronchial lesions* are of considerable importance in tuberculosis in children. Involvement of the bronchus is almost invariably from a contiguous lesion, rarely by direct infection from an outside source. A small bronchus is occasionally compressed or eroded by extension of an adjacent parenchymal lesion. By contrast, involvement of the larger bronchi is relatively frequent from contiguous tuberculous lymph nodes in the hilar area. It is current practice in our Clinic to examine bronchoscopically all children with enlarged tuberculous lymph nodes.

*Intraluminal lesions* are produced by extension of the tuberculous process from an adjacent lymph node through the bronchial wall with establishment of an ulcerative or granulomatous lesion. The ulceration may permit entrance of infected tuberculous material, dissemination of it to other portions of the tracheobronchial tree, and establishment of one or more new lesions at remote sites (bronchopneumonia). Granulomatous lesions may partially or completely obstruct the lumen of the bronchus.

An *extraluminal lesion* is a partial or complete occlusion of a bronchus by enlarged adjacent and usually adherent tuberculous lymph nodes without erosion through the bronchial wall.

When a bronchus is partially obstructed by compression from without or by an intraluminal granulomatous lesion to a degree sufficient to interfere with the flow of air, the portion of the lung supplied by the bronchus becomes emphysematous (Fig. 131). When the obstruction is complete, absorption atelectasis

FIG. 131. Obstructive emphysema of the right lung secondary to a granulomatous intrabronchial lesion. A, Inspiratory phase; B, expiratory phase, showing failure of right lung to contract, and shift of heart and mediastinal structures to left; C, film taken 24 hours after bronchoscopic removal of tuberculous tissue from right main stem bronchus, showing normal aeration of right lung.

lectasis occurs (Fig. 132). In each instance there may also be a tuberculous pneumonitis in all or part of the involved pulmonary area (Figs. 133, 134).

Intrabronchial lesions may be responsible for cough, which may be brassy and may also be productive of variable amounts of sputum. When the lesions are in the major bronchi, they may be seen bronchoscopically. Biopsy material can often be obtained for histologic and cultural diagnostic purposes, and on occasion sufficient material can be removed to restore the bronchial airway.

*Caseous bronchopneumonia* may be localized in one area of the lung or widely disseminated. Material from a tuberculous focus in the parenchyma or in a lymph node discharged into a bronchus in a state of liquefaction is likely to be more widely distributed than when it is in a less fluid, caseous state. The lesions are particularly likely to be distal to the portion of the lung supplied by the eroded bronchus where conditions for localization are good, owing to interference with respiratory mechanics (Fig. 133). In some instances all lobes are involved (Fig. 134).

Children with caseous bronchopneumonia tend to be quite sick. There is usually fever, malaise and, not infrequently, a loose, productive cough. The physical findings vary considerably. There may or may not be impairment to percussion, bronchial breathing or rales. If there is cavity formation, there may be pectoriloquy unless the lesion is too deeply situated. The extent of the involvement can be determined only from the roentgenogram. Tubercle bacilli can usually be discovered in the sputum or lavaged gastric contents. Recovery without antimicrobial treatment is possible, but the prognosis in this type of tuberculous involvement is generally grave. Specific antibacterial therapy is indicated (see p. 465).

*Pulmonary lesions of hematogenous origin* may be roentgenographically indistinguishable from lesions described as noncalcified pulmonary foci, extensive pulmonary infiltrations, caseous bronchopneumonia and apical and infraclavicular lesions. The possibility that such lesions may have their origin by hematogenous dissemination is mentioned merely to point out the various means of origin of the different tuberculous lesions. Among the hematogenous pulmonary lesions, only acute miliary tuberculosis is clinically distinctive.

*Acute miliary tuberculosis* is a blood-borne infection characterized by multiple tubercle

FIG. 132. Atelectasis of right middle and lower lobes secondary to tracheobronchial tuberculous lymphadenitis and an endobronchial granulomatous lesion in a Negro child 4 years of age. Gastric washings were positive for tubercle bacilli. Two months prior to the date of the exposure for the film the child suffered a partial bronchial occlusion which resulted in obstructive emphysema. Subsequently complete bronchial occlusion resulted in absorption atelectasis illustrated here. At this time a portion of the endobronchial granuloma was removed endoscopically. There was no immediate effect, but re-expansion occurred over the next 2 months.

formations. It is more frequent in infants than in older children; beyond infancy, miliary tuberculosis occurs more frequently in the Negro than in members of the white race. Practically all organs of the body may be involved, as may any serous membrane. The latter appear to be less frequently affected by direct hematogenous spread than by rupture of a contiguous tuberculous focus. The distribution of the lesions may be limited to the lungs or may include other viscera—for example, the liver, kidneys, spleen and brain. Tubercle bacilli become lodged in the small capillaries; a lesion develops at each site, and necrosis tends to develop rapidly in each of the small foci. If the life of the child is prolonged for a sufficient time, there is an epithelioid response. It is during this latter stage that the lesions in the lungs become visible on the roentgenogram.

The symptoms are usually those of a general infection. The onset may be abrupt, although at times it is insidious. Fever soon develops and tends to run an irregular course, frequently with peaks as high as 103° or 104° F., and the patient appears extremely ill. Initially there may be no physical signs

FIG. 133.

FIG. 134.

FIG. 134. Appearance of lungs at 9 years of age, after recovery (prior to availability of specific antimicrobial therapy).

to indicate the extent of the involvement. The spleen is often enlarged and the abdomen distended, and these findings with the high fever and absence of other physical findings suggest the possibility of typhoid fever. At

times the pulmonary manifestations may be those of generalized obstructive emphysema, and acute bronchiolitis may be suspected. Localized signs which disclose the true identity of the infection frequently do not appear until the last week or so of the illness in the untreated patient. Fine crepitant rales may be heard at this time over all portions of the chest, and the roentgenogram which previously failed to reveal pulmonary changes will show the characteristic, widely distributed miliary lesions, which have a mottled appearance and are frequently described as resembling snowflakes (Fig. 135). The white blood cell count is not distinctive; it may be increased, but leukopenia is perhaps the more frequent response.

Death usually occurs within four to six weeks in untreated cases. Whereas the mortality rate formerly approximated 100 per cent, recovery is now possible in the majority of instances if treatment is instituted sufficiently early (see p. 465).

*Apical and infraclavicular lesions* are most commonly seen in adult life and are often termed "adult tuberculosis," "apical tuberculosis" or "reinfection tuberculosis." They are relatively uncommon before the adolescent period, when they become the most frequent type of tuberculous involvement, being more frequent in females than males. These lesions have generally been considered to be the result of reinfection tuberculosis, their tendency

FIG. 135. Miliary tuberculosis of the lungs in a white boy 3 years of age. His mother had pulmonary tuberculosis. The physical findings were fine, crackling rales throughout both lungs. Death occurred shortly after this roentgenogram was taken. The tuberculin reaction was positive.

to remain localized and the absence of any extensive involvement of the regional lymph nodes being attributed to an altered response of the host because of a previous infection with the tubercle bacillus. It is now known that lesions will develop in the upper portions of the lungs in previously tuberculin-negative as well as tuberculin-positive adolescents and young adults which are clinically indistinguishable. For this reason these lesions are described simply on the basis of their location and roentgenographic appearance.

The clinical course of individual lesions varies, but in general they can be grouped in three categories. In some there is retrogression toward healing almost from the time of recognition; in others the lesion is quite indolent and resists healing. In this latter type, activation of the lesion may be associated with any factor which lowers the host's general resistance. In the third type the lesion is persistently progressive, and there is destruction of lung tissue with cavitation.

The symptoms and physical findings are also variable. In some instances no symptoms whatever can be elicited, and the diagnosis is made only roentgenographically. In others there may be the general symptoms of a chronic infection (p. 460). Physical examination may or may not reveal fine rales; when present, they are likely to be most consistently detected at the beginning of an inspiration which follows a slight cough after forced expiration. Cavity formation of any extent can usually be suspected on the basis of bronchophony and pectoriloquy. The diagnosis is established by roentgenographic examination, the detection of tubercle bacilli in the sputum or lavaged gastric contents, and upon the response to the tuberculin test. It is necessary to recognize that essentially similar lesions can apparently be produced by coccidioidomycosis and histoplasmosis.

*Tuberculous pleuritis* may occur as a dry fibrinous pleurisy, as a serous effusion, and rarely as a necrotic involvement of the pleura stemming from a contiguous caseous focus in the lung. Most often the reaction is a serous one. Though the total number of tuberculous effusions is decreasing, it is still good judgment to regard all serous effusions as tuberculous until proved otherwise. The process is nearly always unilateral.

Children rarely have complaints suggestive of pleural involvement. Occasionally during the dry stage there may be pleural pain with limitation of respirations on the affected side. Rarely an effusion may become so extensive

that there is actual bulging of the intercostal spaces, so that there is respiratory embarrassment. The presence of a pleural effusion is usually suspected from physical findings, and the diagnosis is confirmed roentgenographically and by pleural aspiration.

The prognosis is generally governed by the pulmonary lesion. Treatment is that of tuberculous infection; aspiration, other than for diagnostic purposes, is indicated only when there are severe symptoms of compression. Absorption of fluid is followed by pleural thickening and adhesions. There is no evidence that drainage will lessen such residuals or prevent reaccumulation of fluid.

#### DIAGNOSIS OF PULMONARY TUBERCULOSIS

The diagnosis of pulmonary tuberculosis is established with certainty by the demonstration of tubercle bacilli in the sputum, bronchoscopically aspirated material or gastric contents. In the absence of such information the diagnosis is based on the history of symptoms and of contact with tuberculous infection, on the physical examination, on the reaction to tuberculin, and on roentgenographic examination of the lungs. Of these, the roentgenogram and the tuberculin test are the most informative. Careful search for tubercle bacilli, however, should always be made.

The evaluation of the child suspected or proved to have tuberculosis should include an estimate of whether the tuberculous lesion is in an active, quiescent or healed stage (see p. 462). In the absence of fever and other clinical evidences of disease such an evaluation is rarely clear-cut.

The appraisal is not complete without a careful search for the source of contact. Frequently open tuberculosis is present in some member of the family or other close associate without his being aware of it (Figs. 136, 137). For this reason tuberculin tests should be performed on the siblings; if the reaction is positive, roentgenograms of the chest should be obtained. All adult members should have a careful physical examination, tuberculin test and a roentgenogram of the chest. Grandparents and other older persons with whom there is contact should be included in this examination, since chronic, open tuberculosis is common among older people. It is a good policy to repeat the examination of the members who have no evidence of disease after an interval of about six months. This plan has the dual advantage of detecting other persons with tuberculosis who require treat-

FIG. 136.

FIG. 137.

FIG. 137. Extensive tuberculous lesion in the chest of the mother, who disclaimed any knowledge of illness or history of tuberculosis in any member of the family. Sputum was positive for tubercle bacilli. Roentgenogram of the mother was taken as part of a survey of the family because of detection of tuberculosis in the child.

ment and of avoiding subsequent contact of the tuberculous child with open tuberculous infection.

**History.** History of possible contact with open tuberculosis should be included in the appraisal of all children with or without symptoms of the disease. Absence of such a history, however, cannot be accepted as evidence against the presence of tuberculosis in the individual child, in members of his family or in other associates, since history of contact is not obtained from the majority of persons found to have tuberculous lesions.

Symptoms of pulmonary tuberculosis vary considerably and to some extent are proportionate to the extent or seriousness of the lesion. However, there are variations in this regard, and it is essential to know that pulmonary infections, even extensive ones, may not be productive of any recognizable symptoms. As a rule, symptoms in children are merely the general ones of chronic infection, such as fatigue, irritability and possibly some degree of undernutrition, and are usually not directly related to the respiratory system. Such symptoms are often overlooked. When all or most symptoms such as cough with expectoration, hemoptysis, fever, fatigue, malaise, loss of weight, and night sweats are present, one may be certain that the lesion is extensive.

**Physical Examination.** The examination should be complete, since tuberculous lesions

may be present in other parts of the body and nontuberculous conditions of the lungs or other parts of the body may be coexistent. Malnutrition may be serious, especially in children of the lower economic groups.

The physical findings of the lungs vary with the nature and extent of the lesion and have been described above. Not infrequently, extensive lesions are found on the roentgenogram when no or only slight abnormal physical signs have been elicited. In general, physical signs of tuberculosis in children tend to be disproportionately few in relation to the extent of the pulmonary damage.

**Roentgenographic Examination.** The common roentgenographic abnormalities have been described and illustrated in the descriptions of the various clinical types of intrathoracic tuberculosis. Those lesions produced by acute bacterial or viral infections can usually be suspected by the clinical course. Chronic intrathoracic disease, such as histoplasmosis or coccidioidomycosis, persistent bronchopneumonia, pulmonary changes following measles or pertussis, lymphoblastomas of the mediastinum, lung abscess, aspiration of foreign material, pulmonary infiltrations due to ascariasis, toxocariasis or *Pneumocystis carinii*, Loeffler's pneumonia, Letterer-Siwe disease and others, are likely to simulate the lesions produced by pulmonary tuberculosis. It should be recognized that inter-

pretation of roentgenograms without adequate knowledge of the history, physical findings and laboratory data will lead to many erroneous diagnoses.

**The Tuberculin Test. Significance of a positive reaction.** A positive tuberculin reaction is evidence that the person has been infected with the tubercle bacillus and is allergic or hypersensitive to its protein. The presence or absence of activity of the lesion cannot be deduced from the extent of the reaction. Properly used, the test constitutes the most reliable method for the selection of children who have had a tuberculous infection and who thus require further examination to determine whether the lesion is active or quiescent.

With certain exceptions, failure to elicit a positive reaction to tuberculin eliminates the possibility of the presence of tuberculous infection. For several weeks after the entrance of tubercle bacilli into the body there is no cutaneous reaction to tuberculin. During advanced or terminal stages of tuberculosis, allergy to tuberculin may disappear; at times it is temporarily inhibited by such nonspecific factors as severe inanition, dehydration and acute febrile diseases. The length of time that allergy to tuberculin will persist after healing of the lesion, and the factors that govern it are not completely understood. In most instances cutaneous allergy persists for years in association with healed lesions.

In the performance of repeated tuberculin tests the question of sensitization to tuberculin is pertinent to the interpretation of all tests subsequent to the initial one. Old tuberculin has been demonstrated to be essentially nonantigenic in the amounts used for ordinary cutaneous testing, as has purified protein derivative (P.P.D.).

**Choice and dose of tuberculin.** Since there is a common allergen for the human and bovine types of tubercle bacilli, the use of tuberculin from human tubercle bacilli is considered adequate. Old tuberculin (O.T.), prepared by concentrating a glycerin broth culture of tubercle bacilli over steam and passing it through a porcelain filter, has long been a standard tuberculin. The principal objection to it is that different batches vary in potency.

Several new tuberculins have been developed which contain no protein other than that of the tubercle bacillus. Of these, only purified protein derivative (P.P.D.) is used at present. Purified protein derivative is the protein of the tubercle bacillus which has

been precipitated from cultures of tubercle bacilli on nonprotein media. Its antigenicity is reduced by heating. It is usually dispensed in the dried state in tablet form, and is dissolved in a measured amount of diluent before use.

The recommendations for dosages of tuberculin by the National Tuberculosis Association (Diagnostic Standards, 1957) are as follows:

For diagnostic and case-finding work and following BCG vaccination, the use of five international units (5 TU) of PPD is recommended as the best single dose, i.e., that amount of any standardized PPD prepared according to acceptable methods which is equal in potency to .0001 mg. of PPD-S, the international standard for human tuberculin. If there is no reaction, or a small one, and suspicion of tuberculous infection still exists, repetition of the test with the same dose is recommended. If there is reason to expect a severe reaction, 1-5 dilution of the above dose may be employed as a preliminary test. This dilution is made with sterile physiological or buffered saline solution.

When OT must be used, it is recommended that the dosage be equivalent to the 5 TU dose of the international OT standard. If the OT used approximates the international standard in potency, the recommended dose would be 0.1 ml. of a 1:2000 dilution (.05 mg.). Unfortunately, there is evidence that some commercial preparations of PPD and OT vary in potency which may lead to variations in results.

There is good evidence that doses greater than 5 TU produce some reactions which are not specific for tuberculous infection. For this reason, the larger doses are of doubtful diagnostic value.

In view of the similarity of certain fungus infections to tuberculosis, it would be wise to perform tests with their antigens simultaneously with the performance of the tuberculin test. This procedure is particularly applicable to histoplasmin in the central part of the United States and to coccidioidin in the far Western states.

**Technique.** There are various methods of performing the tuberculin test, such as the scarification or cutaneous test of Pirquet, the intracutaneous test of Mantoux and the patch test of Vollmer. The percutaneous test of Moro is not used in this country, and the conjunctival test of Calmette is not a safe procedure. In clinical practice or when large numbers of tuberculin tests are to be performed, the intracutaneous method is the one of choice.

For the *intracutaneous test* a 1-cc. tuberculin type syringe graduated to 0.1 cc. and a 27-gauge, short-bevel needle should be used. The injections should be made intracutaneously and not subcutaneously. The tubercu-

lin is so diluted that the testing dose is contained in 0.1 cc. of the diluent.

Tuberculin is heat-stable, and it is practically impossible to remove traces of it from syringes or glassware by ordinary methods of cleaning. For this reason a syringe for tuberculin should be restricted to this testing material and should never be used for any other skin-testing solution. Thus, if a cutaneous reaction was obtained from Schick testing material injected from a syringe previously used for tuberculin, one could not be certain whether the reaction resulted from the Schick material or from the tuberculin.

Recommendations for interpretation of the tuberculin test according to the Diagnostic Standards (1957) of the National Tuberculosis Association are as follows:

The intracutaneous tuberculin test (Mantoux) with either PPD or OT should be read 48 to 72 hours after the injection. Readings should be made in a good light, with the arm slightly flexed. Response to injection is classified on the basis of induration as noted by gentle palpation and stroking with the fingers and not by inspection alone. Reactions should be measured in millimeters at the largest transverse diameter and this measurement recorded.

It has been customary and is recommended that induration over 5 mm. in diameter be regarded as a positive test. There is now some evidence that a better dividing point might be 8 or 10 mm. since almost all patients with active tuberculosis have reactions this size or larger, and smaller reactions may be non-specific. However, the data are inconclusive at this time, and for that reason it is recommended that the exact measurements of reactions be recorded . . . and that [for] persons with reactions over 5 mm., . . . the test should be repeated [and] also if there is redness over 10 mm. in diameter without associated induration. Such redness may be the result of an injection made too deeply.

In extremely severe reactions to the intracutaneous test the inflammation may be decreased and sloughing of the necrotic center at times avoided by prompt application of an ice compress and administration of a corticosteroid.

The *Vollmer patch test* is not as efficient in eliciting positive reactions as the 5 TU dose of PPD and OT. Since, however, it is fairly widely used, a description of the technique and interpretation of the reaction are included here.

The "patch" is applied to the intrascapular area. The skin should be rubbed briskly with some defatting solution such as acetone or ether and permitted to dry. The adhesive is then warmed over a flame or in the palm of the hand and firmly applied. It is removed after forty-eight hours and the test

is read after a second forty-eight-hour period. A positive reaction to the patch test consists of a reddened *indurated* area or several more or less distinct *papules*.

**Bacteriologic Examination.** Tubercle bacilli can usually be isolated in children with active lesions if a diligent search is made. It is the only means for establishing an absolute diagnosis of tuberculosis. There are three principal means for detection of the tubercle bacillus: (1) by direct smear and staining of sputum, cerebrospinal fluid or discharges from such lesions as draining lymph nodes and sinuses of osseous lesions; (2) by guinea pig inoculation of any of these materials; and (3) by cultural methods on artificial media. The last is the most effective. In infants and children who are liable to swallow sputum the lavaged contents of the fasting stomach provide the best source of material for examination. The lavage should be performed early in the morning before the usual breakfast time.

Appropriate studies should always be performed to determine that the acid-fast bacilli isolated are *M. tuberculosis* and not other (atypical) acid-fast bacilli, so-called photochromogens and nonphotochromogens. These bacilli occasionally cause infections in lymph nodes and are also found in the bronchial secretions of patients with chronic bronchopulmonary disease. The significance of these organisms in the production of infection in human beings is not clearly defined. At times they appear to be saprophytes, and on rare occasions appear to be responsible for tuberculosis-like infections. It also appears that some of them are antigenically related to the tubercle bacillus and may induce hypersensitivity which can be elicited by the usual tuberculin test.

**Evaluation of Clinical Activity.** The diagnosis of tuberculous infection is not complete without determining whether the lesion is active or quiescent. When there are such obvious signs of clinical activity as fever and malaise, no further evidence is required. When there are no apparent manifestations of active infection, however, other measures must be used. These include sedimentation rates, blood cell counts, serial roentgenograms, response to exercise and particularly continued observation of the child's apparent well-being and his growth pattern. Rectal temperature should not be taken for at least a half hour after active exercise, since it is normally elevated for a short time after

physical activity. Failure to recognize this fact has often been responsible for unnecessarily confining a child to bed or to reduced activity.

### PROGNOSIS

Most children recover from the primary tuberculous infection, and the majority are unaware of its presence even during its active phase. The realization that recovery is frequent has resulted in the conclusion by some clinicians that the primary infection is a benign lesion. There is an apparent failure to recognize the relatively high fatality rate during the first two years of life, as well as the fact that hematogenous and bronchogenic lesions originate from the primary focus and, in such instances, are in reality a part of the primary infection.

The mortality has been relatively high in the first few years of life and during adolescence (Figs. 123, 124, p. 450). However, the prognosis of pulmonary as well as of other forms of tuberculosis has been tremendously improved by the use of antimicrobial agents. Death, except in tuberculous meningitis, almost never occurs except in patients who are not treated or in whom the diagnosis is made in the terminal phase of the disease. Antimicrobial treatment of pulmonary tuberculosis has resulted in a striking decrease in hematogenous lesions. This observation has led to an extensive clinical trial (p. 464) with the prophylactic administration of isoniazid to young children with possible tuberculin reactions with or without roentgenographically demonstrable lesions and to older children who are known to have become tuberculin-positive within recent months on the possibility that the progression of the localized lesion could be averted and that hematogenous dissemination would be lessened (see Treatment).

### PREVENTION

The only certain means for the prevention of tuberculosis is avoidance of contact with infected persons. Maintenance of an adequate nutritional status and avoidance of fatigue and of debilitating infections are factors in the preservation of the body's natural resistance, but none of them is sufficient to prevent infection.

As yet no certain method has been developed for production of a solid, artificially induced specific immunity.

**Identification of Tuberculous Contacts.** Perhaps the most important measure for the

prevention of tuberculosis in children would be frequent examination of all adults for the presence of tuberculosis. The photofluorographic film is especially serviceable as a survey medium. However, roentgenographic diagnosis is not infallible, and abnormal roentgenographic shadows must be further evaluated by skin tests with tuberculin and fungous antigens and by bacteriologic examinations. Another method of approach is the selection of candidates for roentgenographic examination by means of the tuberculin test. In pediatric practice all children should have a tuberculin test at intervals of two to three years.

In view of the high morbidity and mortality rates for tuberculosis in the crowded sections of the larger cities where poor housing conditions prevail, it is obvious that correction of these factors is an important public health measure.

**Milk.** If at all possible, only pasteurized milk from tuberculosis-free cattle should be used for the feeding of infants and children. Unpasteurized milk, except certified, should not be used without boiling.

**Artificial Immunity.** There have been numerous attempts to develop a satisfactory method for the stimulation of artificial immunity against tuberculosis. Of these, only BCG (*Bacillus of Calmette and Guérin*) vaccination merits continued use. The vaccine is composed of bovine tubercle bacilli whose virulence has been reduced by special cultural procedures. Administration of the vaccine to animals or man produces a limited immunity to reinfection with virulent tubercle bacilli. Intradermal injections seem to be somewhat more effective than subcutaneous ones and less likely to result in indolent ulcers. An occasional infant vaccinated during the first few months of life may acquire suppurative adenopathy, but such a complication almost never occurs in older infants or children. The usual intradermal dose is in the range of 0.1 or 0.15 mg. of freshly prepared vaccine. Positive tuberculin reactions can be expected to develop in most instances after inoculation.

Controlled studies, chiefly in the Scandinavian countries and in the United States, have shown that BCG vaccination produces definite though incomplete protection against tuberculosis. There is general agreement among public health authorities that BCG vaccination is indicated for children who live in areas with high tuberculosis mortality rates and for children who have intimate contact

with persons with inactive or "arrested" tuberculosis.

At present BCG vaccine is prepared in only a few laboratories. Its distribution from these laboratories is usually controlled by local or state health departments.

**Chemoprophylaxis.** In some areas where exposure to tuberculosis is highly probable, trials are under way to determine whether the daily administration of isoniazid to tuberculin-negative persons is an effective and safe prophylactic measure.

#### TREATMENT

The basis for selection of patients for antimicrobial therapy has changed materially in the past few years. Now it is generally agreed that all children with demonstrable active lesions of whatever order and in whatever location of the body should receive such therapy. In addition, it is recommended that all tuberculin-positive children up to three or four years of age and all older children who are known to have become tuberculin-positive within recent months should receive isoniazid in doses of 10 to 20 mg. per kilogram per day for about one year whether or not they have demonstrable lesions. The reasons for this changed policy are largely the effectiveness of isoniazid in the control of progressive lesions, the low degree of its toxicity and, in particular, its apparent effectiveness in the prevention of hematogenous dissemination.

The most useful drugs in the treatment of tuberculosis are isoniazid, streptomycin and aminosalicylic acid. Agents which have occasional usefulness despite their greater limitations include kanamycin, Promizole, Promin, neomycin and viomycin.

*Isoniazid* is the most active and useful of the available agents. It can be administered orally or parenterally. Its toxicity is low, being well tolerated over long periods of time, provided the daily dose does not exceed 10 to 20 mg. per kilogram per day. The emergence of drug-resistant organisms is not rapid, and it can be used as a single agent in many patients with the less serious forms of tuberculosis. The patients with progressive, localized lesions, miliary tuberculosis and meningitis should receive another agent during the early part of their treatment (Table 71). Some adults who received isoniazid for a long time have had convulsive disorders. So far as known, such complications have not been observed in infants and small children. Such reactions have been minimized or averted by the continuous administration of pyridoxine.

*Streptomycin* is an active agent against *M. tuberculosis*, and its use is probably indicated in addition to isoniazid in all serious tuberculous infections. The drug must be administered by intramuscular injection. Long-term treatment is occasionally complicated by labyrinth disorders and less often by deafness, but these are uncommon if the drug is administered only once a day or less frequently. Streptomycin should not be used as the only antituberculous agent, owing to the rapid emergence of streptomycin-resistant organisms. This process can be retarded if another agent is administered concurrently. Dihydrostreptomycin is not recommended, since deafness is a common sequel.

*Aminosalicylic acid* (para-aminosalicylic acid) is tuberculostatic, but is not as effective as either streptomycin or isoniazid. It rarely produces toxic reactions other than gastric irritation, which is occasionally sufficiently severe to prevent its administration. Drug-resistant tubercle bacilli have been infrequently observed after prolonged use of aminosalicylic acid as the sole therapeutic agent. Its value as an antibacterial agent is increased because it inhibits the development of resistance by tubercle bacilli to both streptomycin and isoniazid, and possibly because it results in increased serum levels of isoniazid by competing with it for acetylation.

*Promin* and *Promizole* are not as effective as aminosalicylic acid or isoniazid. Furthermore, both Promin and Promizole can cause serious toxic reactions. Their use, therefore, is rarely indicated.

*Kanamycin* is almost as effective as streptomycin in the treatment of tuberculosis. It does, however, have a slightly greater tendency to produce deafness when used for a prolonged time. Kanamycin does not exhibit cross-resistance to streptomycin, and it can be used in the occasional instance when streptomycin-resistant organisms emerge. Kanamycin is less toxic than neomycin and viomycin. The latter two drugs can cause temporary or permanent renal damage. These agents have been used mainly in the treatment of adults in whom streptomycin-resistant tubercle bacilli have developed. There would seem to be little place for them in the treatment of tuberculosis in children.

Preliminary observations suggest that *corticosteroid therapy* in conjunction with antimicrobial drugs is beneficial in patients with endobronchial granulomas, other severe obstructive lesions of the bronchi and in those with pleural effusions. Corticosteroid therapy

is reported to cause improvement, often within one week, but should be continued for approximately two months even when symptomatic improvement is prompt.

Suggested plans for antimicrobial treatment of the various clinical forms of tuberculosis are detailed in Table 71.

When patients with progressive pulmonary tuberculosis are treated by the suggested plan, symptomatic improvement is usually noted in two to four weeks. Cough decreases, fever declines, and there is increased appetite and sometimes gain in weight. Improvement, as measured by changes in the roentgenograms of the chest, is slow, but extension of the lesion rarely occurs.

Patients with miliary tuberculosis tend to show somewhat more rapid improvement in response to treatment. There is apt to be regression or even disappearance of the miliary densities observed in the roentgenograms within six to ten weeks from the start of treatment. Coexisting extensive pulmonary lesions follow the same pattern of slow improve-

ment noted with other progressive pulmonary lesions. Although meningitis is now an infrequent complication during the treatment of pulmonary tuberculosis when isoniazid is being administered, it is recommended that the cerebrospinal fluid be examined if there is any manifestation to suggest its presence. If meningitis develops, the patient should be treated as outlined on page 470.

*The use of antibacterial agents in the treatment of pulmonary tuberculosis does not eliminate the need for symptomatic and other general therapy.*

Children with nonprogressive primary tuberculous lesions, whether or not they are receiving isoniazid, require no special care beyond that of assurance of adequate nutrition, avoidance of fatigue, prevention of exposure to open tuberculous infection and regular physical examinations, including roentgenograms of the chest. Active immunization against pertussis and passive immunization for measles, whenever exposed, are desirable for children with tuberculous lesions, as is the

Table 71. Suggested Schedules for Antimicrobial Therapy of Pulmonary Tuberculosis in Infants and Children

<i>Type of Disease</i>	<i>Drug<sup>1</sup></i>	<i>Total Daily Dose per Kilogram of Body Weight</i>	<i>Duration</i>
Positive tuberculin reaction in a child under 3 or 4 years of age or a positive tuberculin reaction recently acquired	Isoniazid	10 to 20 mg. (total daily dose should rarely exceed 500 mg.) <sup>2</sup>	One year
Asymptomatic pulmonary tuberculosis	Isoniazid	10 to 20 mg. <sup>2</sup>	One year
Progressive pulmonary lesions; progressive apical and infraclavicular lesions; pleurisy; miliary tuberculosis	Isoniazid	10 to 20 mg. (total daily dose should rarely exceed 500 mg.) <sup>2</sup>	12 to 18 months or for a minimum of 6 months after lesion appears to be inactive
	Streptomycin	20 to 40 mg. in one dose per day (dose not to exceed 1.0 gm./day)	Daily for 1 to 2 months, then 2 to 4 times weekly for 3 to 6 months (concurrently with isoniazid)
	or Aminosalicylic acid (PASA)	300 to 500 mg.	For duration of isoniazid therapy. If streptomycin is given initially, then substitute PASA for it after its discontinuance. Some prescribe it only for an arbitrarily determined shorter time

1. See text for use of corticosteroids.

2. The smaller doses are used for large and overweight children. Pyridoxine is prescribed with isoniazid for adolescent children by some clinicians to lessen the likelihood of convulsive disorders.

early treatment of all intercurrent infections in order to lessen the possibilities of activation of the tuberculous process.

Children who are sick with tuberculosis as evidenced by fever, malaise, loss of weight, anemia, abnormal white blood cell count, increased erythrocyte sedimentation rate and/or roentgenographic evidence of progression of the tuberculous lesion require general medical care.

*Bed rest* is indicated until there are substantial evidences of improvement. Other than maintenance of the necessary isolation procedures (p. 397), the management is that of any child with a chronic illness, whether in an institution or at home.

The *psychologic attitudes* of the child and his family are important. An atmosphere of cheerful optimism should prevail in which the child is provided some regularity of schedule and even some purposeful duties which can be accomplished in bed. Except in severe illness, there is no reason why the child should not be permitted to continue with his schoolwork.

*Fresh air and sunshine* are not important in treatment except as they add to the child's sense of well-being. Heliotherapy is not contraindicated except in excessive amounts in patients with pulmonary lesions. Burning of the skin should be scrupulously avoided. Tanning is permissible if it is acquired gradually.

The *nutritional intake* should be adequate, but forced feeding should be avoided. Special attention should be given to the protein, mineral and vitamin content of the diet. There is need for additional amounts of vitamin C; 100 to 200 mg. of ascorbic acid will meet the daily requirement in the average case. There is no reason why this cannot be supplied by natural foodstuffs. Vitamins of the B complex should be supplied in amounts somewhat in excess of average requirements. There is no need for excessively large doses of vitamin D, nor is there need for more than a quart of milk a day. Fresh fruits and vegetables should be given freely. Feeding of tuberculous infants is, with the exception of those with gastrointestinal disturbances, not different from that of other infants. Low residue diets should be prescribed when there is chronic intestinal involvement.

*Surgical procedures*, other than bronchoscopy, are rarely indicated in the treatment of pulmonary tuberculosis in infants and children. Collapse treatment is occasionally indicated in older children and adolescents. Lobectomy is occasionally required for those

with persistent atelectasis or bronchiectasis following endobronchial lesions.

## EXTRATHORACIC TUBERCULOSIS

### TUBERCULOUS INFECTION OF TONSILS AND CERVICAL LYMPH NODES

Infection of the cervical lymph nodes is, in most instances, secondary to tuberculous infection of the tonsils, which may constitute the primary lesion or may be secondary to a pulmonary lesion. When the tonsillar infection is primary, it constitutes, in conjunction with the cervical lymph node involvement, a primary tuberculous complex. Such infections have become much less frequent with the decrease in incidence of bovine tuberculosis.

**Clinical Manifestations.** The local manifestations of tuberculosis of the cervical lymph nodes vary from slight enlargement of a single node to involvement of a number of them. The nodes of both sides are frequently affected, although usually more on one side than on the other. The initial inflammatory changes are responsible for the enlargement, and at this stage the node or nodes are discrete, firm and usually freely movable. When the lesions of the individual nodes become caseous, however, there is a tendency to erosion of the capsule, and the nodes in the immediate vicinity become matted together in a single, irregular nodular mass, often with variable degrees of firmness in different portions. The mass becomes attached to other

adjacent structures and to the overlying skin and is no longer freely movable. The skin is often discolored and may be retracted in areas by the underlying adhesions, thus having an uneven contour.

If liquefaction of the caseous mass occurs, rupture into the adjacent tissues is likely. If the overlying skin is perforated, as it often is, a draining sinus results which persists a long time. There may be only a single sinus, or, as new areas break down, other sinuses may be formed. When the nodes of the retropharyngeal area are involved or when the discharge from other nodes or from an osseous lesion in the cervical vertebrae finds its way into the retropharyngeal area, a chronic, burrowing retropharyngeal and retroesophageal abscess results. The draining sinuses on the surface of the neck persist until the involved lymphatic tissue is broken down and evacuated, the course without antimicrobial therapy being measured in months and, at times, in years. Indolent skin lesions frequently result, and healing leaves permanent scarring, discoloration and contractural deformities.

Not all tuberculous lymph nodes undergo such a course, and resolution may take place before extensive caseation occurs, or the caseous mass may become calcified and a number of nodes remain matted together and indurated without suppurating. When calcification is present, it may be visualized roentgenographically. During the period of active inflammation there may be a low grade fever and other evidences of chronic infection.

**Diagnosis.** The tonsillar lesion can be identified only by microscopic examination of the enucleated tonsil.

The differential diagnosis is from other conditions which may cause chronic lymphadenitis, and should include the lymphoblastomas, Hodgkin's disease, actinomycosis and cat-scratch disease. Particular difficulty is experienced in residual or low grade cervical lymphadenitis associated with chronic upper respiratory tract infections. The likelihood of a tuberculous etiology is increased in the presence of a positive tuberculin reaction, but the diagnosis is established only by isolation of tubercle bacilli from the excretions of a draining sinus or by microscopic examination of an excised lymph node.

**Prognosis.** This depends upon the stage at which diagnosis is established and treatment instituted. Most lesions eventually heal even when untreated. In such instances contractural deformities may be expected.

**Treatment.** Treatment varies with the stage of the lesions at the time of diagnosis. If the lymph nodes are still discrete, excision of the involved ones by careful surgical dissection is recommended. Streptomycin, 10 to 20 mg. per kilogram per dose, should be administered two or three times at intervals of twelve hours prior to operation. After excision streptomycin is continued for approximately two weeks, or longer if the operative site shows any drainage. Isoniazid is also administered postoperatively for twelve months in doses of 10 to 20 mg. per kilogram per day.

If the lymph nodes have ruptured spontaneously prior to establishment of the diagnosis, antibacterial therapy as recommended for progressive pulmonary tuberculosis in Table 71 should be instituted. If drainage persists after two weeks of treatment, secondary bacterial infection is probably present, and other antibiotic therapy should be given in addition to the antituberculosis therapy. In most instances the sinus tracts will close within several weeks. Surgical excision can then be performed; antimicrobial therapy should be carried out postoperatively as recommended above.

If the mass of lymph nodes is so extensive that surgical excision is not feasible, a trial of antimicrobial therapy as recommended for progressive pulmonary lesions in Table 71 is suggested.

Whether tonsillectomy should be performed several weeks after excision of the lymph nodes is not established.

#### INFECTION OF OTHER SUPERFICIAL LYMPH NODES

Tuberculosis of other superficial lymph nodes, such as those of the axilla, groin or occipital region, may occur, but is less frequent than infection of the cervical lymph nodes. The course of the infection is that described for cervical lymphadenitis.

#### INTRA-ABDOMINAL TUBERCULOSIS

Tuberculous enteritis may occur as a primary infection or may be secondary to a pulmonary lesion, the bacilli being transported in swallowed sputum. The stomach is rarely infected. Progressive ulcerative enteritis is more likely to be a secondary than a primary infection and is usually associated with a well advanced pulmonary process. In both primary and secondary lesions the mesenteric and, at times, the retroperitoneal lymph nodes are involved. In primary infections the intestinal

lesion is usually relatively unimportant and is overshadowed by the lymph node involvement, whereas the situation is essentially reversed in secondary infections. Tuberculous peritonitis may be part of a generalized hematogenous infection, but more frequently results from rupture of a caseous mesenteric lymph node or by extension from an ulcerative intestinal lesion. Tuberculosis of the liver and spleen is usually a part of generalized miliary tuberculosis. The incidence of primary intestinal tuberculosis in this country has decreased tremendously in recent years, owing to the almost complete eradication of bovine tuberculosis. Secondary intra-abdominal lesions are relatively uncommon during childhood.

#### TUBERCULOUS ENTERITIS

Small tuberculous ulcers frequently produce no symptoms and are discovered only at autopsy. With more extensive lesions the symptoms are those of ileocolitis with tenesmus and chronic diarrhea. There may be gross hemorrhage, but more often there is only slight bleeding. That the lesions are tuberculous may be suspected from the chronicity and also from the presence of tuberculous infection elsewhere in the body, especially in the lungs. Abdominal distention and tenderness may be present; there is irregular fever, wasting is often great, and anemia and debility are marked. In advanced cases the symptoms of tuberculous peritonitis may also be present.

**Treatment.** The diet should be low in residue, but should have adequate caloric value and be high in vitamin content. In the more severe cases parenteral administration of vitamins may be indicated, as at times may be the administration of amino acids, blood and plasma. Antispasmodics such as paregoric and belladonna preparations may be given for the relief of tenesmus. Antimicrobial therapy as outlined in Table 71 for progressive pulmonary tuberculosis should be employed.

#### TUBERCULOUS PERITONITIS

The incidence of tuberculous peritonitis has decreased in the past decade and is now rare in the United States. Scattered miliary tubercles may be found upon the peritoneum in acute, generalized miliary tuberculosis. Tuberculous peritonitis usually originates from erosion of a caseous or liquefied lesion in a mesenteric lymph node; less often from an intestinal lesion which has penetrated through

the outer coat, usually without causing perforation.

**Clinical Manifestations.** The onset is as a rule insidious and is characterized by gradually increasing debilitation, vague or slight abdominal pain or tenderness and low grade fever. The onset may, however, be more abrupt and severe and may be suggestive of appendicitis when the pain and tenderness are located in the right lower quadrant. Vomiting may occur, but usually is not marked, and there are no characteristic changes in the stools except in the presence of an associated enteritis. Often there is nothing on which to base the diagnosis until attention is directed to the gradually increasing distention of the abdomen.

Clinically, tuberculosis peritonitis has been divided into three general types: (1) the ascitic form, (2) the fibrinous or plastic form, and (3) the caseous or ulcerative form. All these processes are frequently present in a single case, and there may be no sharp distinction into a particular clinical pattern.

**Prognosis.** The natural course of tuberculous peritonitis is essentially a chronic one. Only in the rare acute ulcerative type does it proceed rapidly. The outcome is determined not only by the type and extent of the local involvement, but also by the nature of the tuberculous lesions of other parts of the body. In general, the ascitic form has the most favorable prognosis, the caseous form the worst.

**Treatment.** The management of tuberculous peritonitis is essentially that of tuberculosis in general. If there is an associated enteritis, the diet should be low in residue; otherwise it may be adjusted to the patient's appetite. There should be adequate calories as well as a high vitamin and mineral content in the diet. Heliotherapy appears to be of some benefit. Antimicrobial therapy as recommended for progressive pulmonary tuberculosis is indicated.

#### TUBERCULOSIS OF THE CENTRAL NERVOUS SYSTEM

##### TUBERCULOMA

Tuberculomas of the brain or spinal cord may be single or multiple, and may or may not be productive of neurologic symptoms. Though they are often recognized only at autopsy, they may be responsible for symptoms of increased intracranial pressure and/or localized peripheral manifestations and in

such instances are indistinguishable clinically from intracranial neoplasms. Intracerebral calcification, which may be demonstrable on the roentgenogram, may be tuberculous in origin, but more often is the result of such lesions as toxoplasmosis, astrocytomas, Sturge-Weber syndrome or an organized hemorrhage. Tuberculomas at the surface of the brain constitute the principal means for infection of meninges.

#### TUBERCULOUS MENINGITIS

Tuberculous meningitis is the principal cause of death from tuberculosis and is most frequent in the first few years of life. It is usually associated with primary tuberculous infections and is most likely to occur within a few months after the initial manifestation of the primary lesion. The incidence is especially high in the Negro race. Frequently it is the initial and only clinical manifestation of tuberculous infection, although it is always a secondary lesion. The primary focus, usually in the lung, need not be extensive, and caseous foci of not more than 1 cm. or so may be responsible for hematogenous spread of tubercle bacilli. Generalized miliary tuberculosis is observed in about 25 per cent of cases.

**Pathogenesis and Pathology.** The observations of Rich and McCordock indicate that the meninges are rarely directly infected by the hematogenous route, but rather are secondarily involved by the discharge of tubercle bacilli into the cerebrospinal fluid from contiguous older caseous foci such as a tuberculoma in the brain or spinal cord or osseous lesions of the vertebrae.

Tubercles are scattered over the pia and the surface of the brain. The dura is tense, the convolutions are flattened, and the arachnoid space and the ventricles contain serofibrinous exudate.

**Clinical Manifestations.** The clinical manifestations may vary, and at times meningeal symptoms are not present until the terminal stage. In general, however, there is a more or less typical pattern which in the untreated child may be divided into three stages: (1) a prodromal stage of irritation, (2) a transitional stage of increased intracranial pressure and meningeal symptoms, and (3) a terminal stage of paralysis and coma. These stages are not sharply demarcated, and not all may be present in a given case.

**Prodromal stage.** The onset is usually slow, with little or no fever, rarely acute with high fever. The initial manifestations are indefinite and often vague. Changes in disposition are

frequent; a good-natured child becomes irritable. Periods of drowsiness are common, but sleep is frequently restless and interrupted. Older children complain of headache. Anorexia, vomiting and constipation are common.

**Transitional stage.** Convulsions may occur during this stage, and the drowsiness becomes much deeper. Most frequent, however, are the evidences of meningeal irritation. There is nuchal rigidity and stiffness of the back and extremities, at times sufficient to produce opisthotonos. The deep reflexes tend to be exaggerated. There may be bulging of the fontanel. Ocular paralyses are common, or there may be nystagmus or strabismus; the pupils are normal or contracted, and hippus may be present. Occasionally there is choking of the disk, and tubercles may be present along the vessels of the choroid. During this stage there is usually a well marked *tache cérébrale* and at times, because of vasomotor disturbances, irregular flushing of the trunk and face. The temperature is usually elevated, but is rarely high. The course is progressive, and the drowsiness tends to be replaced by stupor.

**Terminal stage.** After a time the evidences of meningeal irritation are replaced by those of paralysis of the final phase of the disease. The child now lapses into a comatose state with cessation of voluntary movement, dilated and unresponsive pupils, insensitivity of the cornea, widespread paralyses, irregular pulse which may be slow or accelerated, and irregular respirations which are at times of the Cheyne-Stokes type. The temperature rises abruptly at the terminal stage, at times to as high as 106° or 107° F., and there may be hyperglycemia and glycosuria. These are terminal manifestations, and death occurs without recovery of consciousness.

**Variations.** The duration of untreated tuberculous meningitis is generally not more than two or three weeks after definite symptoms appear. In general, each of the three stages described averages about a week, although the initial one may be somewhat longer and the last stage shorter. In unusual instances, however, the terminal stage may be prolonged for several weeks. The course is also subject to other variations. The prodromal stage may be absent, with the onset sudden and the total course brief. Temporary improvement and even remission for weeks or months have been recorded. As a rule, the disease in infancy is more abrupt in onset than in childhood; generalized convulsions

are more frequent, the symptoms are less characteristic, and the course is shorter. A clinical course unmodified by treatment is now rarely seen.

**Diagnosis.** A positive tuberculin reaction is supportive but not confirmatory evidence. In the terminal stage cutaneous sensitivity to tuberculin may be lost. The white blood cell count is not characteristic; in the early stages, if there is a change in the total count, it is likely to be decreased. In the late stage there is often a moderate leukocytosis.

The cerebrospinal fluid provides the most important data, but an absolute diagnosis can be made from it only by isolation of tubercle bacilli. The fluid may be clear or only slightly turbid, the so-called ground-glass appearance. It is practically always increased in pressure and amount. The cell count ranges from 20 to about 500 per cubic millimeter. Though there is occasionally a predominance of polymorphonuclear cells in the early course of the disease, this is rarely observed, since, by the time there are sufficient symptoms to suggest the necessity for spinal puncture, the cells present are mainly lymphocytes. The protein content of the cerebrospinal fluid is increased and is often more than 100 mg. per 100 ml.; the sugar content is usually decreased, and the total chlorides are usually significantly reduced in the latter phase of the disease.

On standing, the cerebrospinal fluid usually forms a fibrinous web or pellicle in which the tubercle bacilli are enmeshed and in which they can be demonstrated on staining. The fluid should also be centrifuged and the sediment examined. When the organisms cannot be demonstrated by direct examination, they usually can be by culture or guinea pig inoculation.

The differential diagnosis is chiefly from other conditions responsible for an increase in lymphocytic cells in the cerebrospinal fluid (see Aseptic Meningitis Syndrome, p. 544). There is rarely any difficulty in the differential diagnosis of the various purulent meningitides, except as their course has been modified by suppressive but inadequate antimicrobial therapy. The demonstration of a tuberculous lesion in some other region of the body is strong supportive evidence in favor of a tuberculous etiology for the meningitis.

**Prognosis.** Complete recovery from tuberculous meningitis is now a possibility. The mortality rate is still high, ranging from 10 to 50 per cent in different series of treated cases, and the incidence of permanent physical and mental residuals among the survivors

is also high. The promptness with which specific therapy is instituted would seem to be a determining factor, although recovery has occurred in patients considered to be hopeless.

**Treatment.** The treatment of choice at this time is a combination of streptomycin and isoniazid and adequate supportive measures.

The plan currently used in our clinic is as follows: streptomycin, 50 mg. per kilogram intramuscularly every twelve hours (but not over 2 gm. per day) until there are signs of improvement, then 20 to 40 mg. per kilogram every other day (but not over 1 gm. per dose) for a total of three to six months; and isoniazid in total daily oral doses of 10 to 20 mg. per kilogram for at least eighteen months. Intrathecal therapy with antimicrobial drugs is not used. In some clinics aminosalicylic acid is administered in conjunction with isoniazid after the streptomycin has been discontinued (see Table 71).

One of the major obstacles in the treatment of tuberculous meningitis is the development of obstruction to the flow of cerebrospinal fluid. In the past various surgical procedures were performed in an attempt to relieve the obstructive lesions, but none was uniformly successful. Attempts have been made to remove the obstructions by lysis of the fibrinous exudate by the action of P.P.D. tuberculin or proteolytic enzymes injected intrathecally. Such efforts are usually ineffective. Reports, chiefly from European clinics, suggest that obstruction to the flow of cerebrospinal fluid can be prevented or at times relieved by administration of a corticosteroid during the first two months of therapy.

Supportive measures include adequate nutrition, which often necessitates gavage feeding, vitamin supplements, attention to fluid and electrolyte balance (see p. 191 for salt-losing syndrome), sedation, prophylaxis against bedsores and early detection and treatment of intercurrent infections.

## SPIROCHETAL INFECTIONS

## SYPHILIS

Syphilis is a chronic infectious disease in which periods of activity with demonstrable signs and symptoms alternate with long periods of latency, when the infection seems to lie dormant, only to appear later in a somewhat modified form. In infancy and childhood, congenital syphilis is much more common than acquired syphilis.

**Etiology.** The causative agent of syphilis, the *Treponema pallidum*, is a slender spiral organism which can be demonstrated by darkfield examination of scrapings from acute exudative lesions. It does not survive long outside the body.

The disease can be transmitted only when the organism enters an abrasion of the skin or mucous membrane or is introduced directly into the blood stream. Infection of the fetus occurs from the mother through the placenta, seldom before the fourth month of intrauterine life.

Syphilis is not a common cause of early abortion. When the infection of the mother is recent and untreated, the fetus is almost certain to be infected. Infants born at term from mothers who have had the infection for some time usually appear normal at birth; they may escape the disease or show manifestations of it later. Fetal syphilis may occur during pregnancies subsequent to one which resulted in the birth of a normal uninfected child from a syphilitic mother; syphilitic infants have been born fifteen to twenty years after the mother became infected. Syphilis is rarely transmitted to the third generation. The father plays no part in transmission of the disease except as he infects the mother.

**Pathology.** *Treponema pallidum* may be found in enormous numbers in fetuses dying of congenital syphilis. In the syphilitic infant there is widespread extramedullary hematopoiesis, similar to that in infants with erythroblastosis fetalis. An extensive inflammatory reaction may also be present, with resultant destruction of tissue and ultimate scarring.

Splenomegaly, osteochondritis and extramedullary hematopoiesis are among the most constant findings in newborn infants dying with congenital syphilis. Pancreatitis, moderate hepatomegaly and syphilitic inflammation of the lungs (pneumonia alba) are also com-

mon. Less frequent findings include involvement of the leptomeninges, bowel, adrenals and hypophysis.

## CONGENITAL SYPHILIS

**Incidence.** The incidence of congenital syphilis depends on the frequency of syphilis in pregnant women, the treatment these women receive and the proportion of live births among those who are inadequately treated. Of pregnancies in untreated syphilitic women, stillbirth will occur in about 30 per cent, and approximately 70 per cent of the infants born alive will have the disease.

**Symptoms.** Since congenital syphilis is acquired through infection of the placenta, the child has no lesion comparable to that of primary syphilis. The two stages in the child are usually termed "early congenital syphilis," which is roughly similar to secondary syphilis of the adult, and "late congenital syphilis," which corresponds somewhat to tertiary syphilis. Certain defects caused by early congenital syphilis last throughout life and are easily recognizable as stigmas in older children and adults.

Syphilitic infants occasionally have manifestations at birth, a feature which usually indicates a severe infection. Most often, however, the infant appears healthy at birth and exhibits symptoms between the second and sixth weeks of life. In some instances there may be no symptoms until the infant is a year or two of age, or even none except in later childhood. Rarely the infection may remain permanently latent.

## EARLY CONGENITAL SYPHILIS

**Clinical Manifestations.** Early congenital syphilis is a much more serious disease than secondary syphilis of the adult. It may resemble septicemia in which all organs of the body are involved. Untreated, it frequently results in death of the infant. General symptoms such as anemia, wasting, restlessness and fever may develop before the local symptoms, or the infant may appear quite well even though the local evidences of disease are marked. The most common localized symptoms are rhinitis, usually known as "snuffles," skin eruptions, pseudoparalysis, and moist lesions around the mouth, anus and genitals. The spleen, lymph nodes and

FIG. 138. Saddle nose in early syphilis.

FIG. 139. Maculopapular eruption of congenital syphilis.

liver are usually enlarged. Septicemia may be caused by bacteria which gain access through the external syphilitic lesions.

**Rhinitis or "snuffles."** This manifestation is generally the first to appear and is rarely absent in the infant with clinically manifest syphilis. Beginning as a swelling of the nasal mucosa, a profuse mucopurulent discharge soon develops which excoriates the upper lip. With ulceration of the mucosa and sometimes of the submucosa, bleeding occurs. Nasal obstruction may interfere with breathing and nursing. Subsequent flattening of the bridge of the nose gives delayed evidence that the cartilages and the base of the nose are involved (Fig. 138).

**Eruption.** Eruptions of the skin are common in the early stage of congenital syphilis. The rash is usually maculopapular, circular and slightly elevated and does not itch (Fig. 139). At first it is bright red, but gradually fades to a brownish color, leaving staining for some time. In Negro children especially the eruption is likely to be circinate. It may involve the entire body or be present only on the face, back and extremities. It usually involves the palms and soles, where the skin is infiltrated, swollen, red and moist with desquamation, or dry, shrunken and scaly with bright or dark spots of eruption (Fig. 140). The region of the eyebrows and sometimes of the eyelashes is often involved in a scaly eruption, with partial or complete loss of hair. The nails may have a pinched appearance with transverse ridges, and there is often a syphilitic paronychia. Sometimes the eruption does not appear until late in the first year, or the early eruption may fade only to recur weeks or months later.

**Mucocutaneous lesions.** Lesions often occur around the nose, mouth, anus and vulva. They are moist and produce fissuring and bleeding. If those around the mouth are deep, they lead to radiating scars or rhagades, one of the stigmas of syphilis. Condylomas, flat raised plaques with moist surfaces, occur around the anus and female genitals (Fig. 141). They may appear early, but more commonly are associated with a recurrence of symptoms. In a child of two or three years of age condylomas may be the only mani-

FIG. 140. Syphilitic scaling of feet in an infant 6 weeks of age. Snuffles and cutaneous eruption developed at the age of 2 weeks.

FIG. 141. Condylomas (condylomata lata) of vulva in a girl 8 years of age. Spirochetes were obtained from the lesions.

festation of syphilis; in older children they may be a manifestation of acquired syphilis.

**Anemia.** Anemia is almost always present and is likely to be marked in severe infections. The anemia may result from the effect of the disease on the bone marrow or from hemorrhage, as, for example, from the nose or periumbilical area. Nucleated red blood cells may be abundant.

**Edema.** Edema is often present. In severe infections the serum proteins reach extremely low levels, and the "swelling" of the child may be one of the initial symptoms recognized by the parent.

**Osteochondritis and pseudoparalysis.** Osteochondritis is one of the most characteristic and frequent lesions of early congenital syphilis. It may be sufficiently marked at birth to enable a diagnosis of syphilis to be made roentgenographically. When severe, it causes, after the first few weeks of life, fractures at the ends of the long bones proximal to the epiphysal lines and separation of the epiphyses. A pseudoparalysis (Parrot's) of the extremity with pain on passive motion then results which is more common in the arms than the legs and usually occurs between one and four months of age. There may be true osteomyelitis of the bones with local periostitis (Fig. 142) and even fractures farther back in the shaft. Mistaken diagnoses of birth injury to the brachial plexus, poliomyelitis or scurvy are sometimes made, though the age of the child and other evidences of syphilis should enable one to avoid this error.

In the fetus, syphilis of the bone manifests itself chiefly as osteochondritis. The line of ossification becomes wider, irregular and indefinite, owing to incomplete ossification and dense cellular infiltration. Granulation tissue is abundant; if this becomes necrotic, there

is disintegration of the bone with separation of the epiphysis, and bone formation ceases at this site. Spirochetes are found in great numbers in such areas and in the periosteum when it is involved. After birth, periostitis is usually also present.

**Hepatosplenomegaly.** The liver is almost always enlarged, and there is usually some jaundice when manifest infection is present. The jaundice, with the anemia, edema and the staining left after a mild eruption, produces the peculiar dirty, whitish brown (*café-au-lait*) appearance of the child. The spleen is usually enlarged to a relatively greater extent than are the lymph nodes.

**Neurosyphilis.** Jeans found changes in the cerebrospinal fluid, with or without clinical evidence of meningitis, in more than a third of cases which showed other early manifestations. Clinical evidence of meningitis, with bulging of the fontanel, opisthotonos and, at times, convulsions is a serious prognostic sign, especially in a child who is poorly nourished and has severe lesions elsewhere. A low grade syphilitic meningitis may cause a mild hydrocephalus, which can be a contributing factor to the peculiar, high square forehead in older syphilitic children. Meningovascular involvement occasionally occurs in infancy and continues into childhood. Children with this type of involvement are mentally retarded and prone to convulsions and transient hemiplegias. Simple meningeal involvement or asymptomatic neurosyphilis usually disappears with treatment. Even when symptoms are present, the cerebrospinal fluid cell count in syphilitic meningitis is seldom over 100 cells per cubic millimeter. The protein level is increased, and that of the sugar is normal; the serologic tests and the colloidal gold curve are positive.

**Roentgenographic Examination.** The roentgenographic changes are always multiple, the findings usually being most evident in the wrists, ankles and knees. There is increased density and widening of the epiphysal line with an area of decreased density behind it. The epiphysal line is sometimes finely serrated. Irregular destructive lesions near the ends of the bones in severe cases are often best seen on the medial surface of the tibia at the knee, where they constitute an almost pathognomonic finding. Periostitis usually involves several bones simultaneously and can be recognized easily in the roentgenogram. The evidences of osteochondritis have usually disappeared by about the sixth month, but periostitis may remain much

FIG. 142. Roentgenogram of forearm (A) and lower leg (B) of infant 6 weeks of age with congenital syphilis. O, Osteochondritis; P, periostitis.

longer, and the bones show great thickening of the cortex.

Periostitis also involves the bones of the skull; when severe, it is at least partially responsible for the peculiarly flat, overhanging forehead which remains as a stigma in children who have been severely infected in infancy. Dactylitis with involvement of both phalanges and metacarpal or metatarsal bones occurs in some instances. Suppuration of the bones and overlying soft tissues is always due to secondary invasion by pyogenic organisms.

**Stigmas.** The child who has had severe syphilis in infancy is usually left with stigmas of the disease. He tends to have a flat face, usually with a high forehead, a small nose with little bridge, and a small mouth which appears slightly drawn together. He often has rhagades or scars around the nose and mouth. Changes in the bones of the skull and face and maldevelopment of the teeth may become evident only as the child grows.

**Teeth.** The deciduous teeth of children with early congenital syphilis are prone to decay, but show no specific deformities. The most common stigma is maldevelopment of the permanent teeth, most often of the incisors and the sixth-year molars. The buds of

these teeth are being formed during the first few weeks of life, when congenital syphilis is most likely to be active. The outstanding defect involves the incisal edge of the middle lobe of the upper central incisors, though all the lobes are undersized at the biting edge. The tooth appears as if it had been pinched together at the incisal margin. The result is a peg-shaped tooth, which at times has a notch in the middle (Hutchinson's teeth, Fig. 143). The cusps of the sixth-year molars may be badly formed and look as if they had

FIG. 143. Hutchinson's teeth in congenital syphilis in a boy 10 years of age.

been squeezed together, thus producing the lobulated mulberry appearance (Moon).

### LATE CONGENITAL SYPHILIS

**Interstitial Keratitis.** This severe and exceptionally uncomfortable lesion of the cornea is the most frequent active manifestation of late congenital syphilis. It does not occur with acquired syphilis, except perhaps that acquired at birth or in early childhood. It may occur as early as four years of age or as late as twenty years, but is most common from the sixth to the twelfth year of life. Photophobia and lacrimation are marked, and the child suffers great discomfort. The inflammation usually begins in one eye, but eventually involves both eyes in most instances. There is vascular infiltration of the deep layers of the cornea, with exudation. Gradually the cornea becomes opaque and appears reddish-gray. The infiltration lasts for weeks or months; though it may be somewhat arrested by treatment, it is not readily healed. Sometimes the second eye becomes involved after treatment has started. Scarring of the cornea and deep corneal vascularization usually remain after the process has healed.

**Neurosyphilis.** This manifestation is unfortunately the second most common lesion of late congenital syphilis and may become manifest from one to ten years of age. The clinical picture is usually that of meningo-vascular syphilis. At times there may be signs of involvement from early infancy with hemiplegia, spastic paralysis or convulsions. More often the child is somewhat mentally retarded, slow in speech, irritable and restless. Even with an acute hemiplegia the child usually has no fever and does not appear very ill. The paralysis often improves, only to recur on the same or on the opposite side. The vascular disease may proceed slowly with no acute episodes and lead to progressively greater mental deterioration, often with decided spasticity and increase in deep reflexes. The pupils may be unequal and fail to react to light. The cerebrospinal fluid shows an increase in cells and protein, a strongly positive serologic reaction and a paretic colloidal gold or mastic curve.

True juvenile paresis with memory defects, delinquencies, delusions and hallucinations occurring after a period of apparently normal development is rare. It is usually late in appearance, not becoming manifest until at least the second decade of life. Juvenile tabes is exceedingly rare. Several of the symptoms

FIG. 144. Saber tibia in a boy 10 years of age.

FIG. 145. Syphilitic perforation of the palate in a girl 10 years of age.

seen in adults are usually lacking, though incontinence of urine is frequent.

**Other Manifestations.** Osseous changes are found in about 15 per cent of children with clinical evidence of syphilis after infancy. The skull and the tibiae are most commonly affected. Although there may be destructive osseous lesions, periostitis is the most common finding. In the tibia, thickening of the anterior surface gives rise to the characteristic outward curving known as *saber shin* (Fig. 144). Pain in the legs may be present at night or after exercise. Gummas may occur in the bones of the skull or in the long bones, where they erode the bone and later involve the skin and produce ulceration and a foul-smelling discharge. They are most common in the nasal septum and palate. Although the gumma may respond to treatment, repair is never complete, and the child is left with a saddle nose or a perforation of the palate (Fig. 145).

Subcutaneous gummas occur most com

monly about the face and on the legs. In the early stages they produce an indurated gray swelling with red edges. As they become necrotic, ulcers with thick, indurated borders are formed.

Arthritis may affect any of the large joints, but is common only in the knees. An effusion into bilateral joints is known as *Clutton's joints*. The lesion is usually painless, is unaccompanied by fever and yields readily to treatment, or may disappear without treatment, leaving no residuals.

Choroiditis, retinitis and optic atrophy are encountered as late syphilitic manifestations. Optic atrophy usually occurs in conjunction with neurosyphilis.

Deafness was apparently more frequent in the past than it is now. Though the pathol-

ogy of syphilitic deafness is not clear, it has been attributed to involvement of the eighth nerve either as a primary lesion or secondary to compression changes in the temporal bone or to involvement of the cochlea. The combination of nerve deafness, deformity of the central incisors, and interstitial keratitis is known as *Hutchinson's triad*.

Visceral lesions are rare in late congenital syphilis; the heart and blood vessels, which are often affected in adults, are almost never involved in children. Paroxysmal hemoglobinuria, a rare disorder which follows exposure to cold or, rarely, exertion, is a manifestation of late congenital or acquired syphilis.

**Differential Diagnosis.** Syphilis seldom produces a single manifestation. "Snuffles" may be mistaken for ordinary coryza. Pseudo-

Table 73. Clinical Manifestations of Congenital Syphilis

	Early Manifestations	Stigmas	Late Manifestations
Skin.....	Maculopapular rash Diffuse inflammation of palms and soles Mucocutaneous lesions about nose, mouth and anus Condylomas <i>Café-au-lait</i> appearance Pemphigus Paronychia Deformities of nails Alopecia	Rhagades	Condylomas Syphilides Gummas
Mucous membrane...	Rhinitis Mucous patches	Saddle nose

paralysis may suggest birth injury, poliomyelitis or scurvy. Scabies, which in infancy usually involves the palms and soles, may be confused with a syphilitic eruption. Enlargement of the liver and spleen is common in many diseases other than syphilis. Transverse ridging of the teeth with poor enamel at the biting edge may be caused by poor nutrition in early infancy, but the characteristic deformity of Hutchinson's teeth is present only in syphilis. Interstitial keratitis and phlyctenular keratoconjunctivitis are often confused; the latter involves both conjunctiva and cornea and has a great tendency to relapses and remissions. The changes of the long bones in early syphilis may be confused with those of pyogenic osteomyelitis, sickle cell anemia or even with infantile cortical hyperostosis, hypervitaminosis A and scurvy.

**Diagnosis.** *Treponema* can often be found in scrapings from moist lesions by means of the darkfield microscope.

The Wassermann test or any one of the flocculation or precipitation tests is extremely reliable in congenital syphilis except during the first six months of life. At birth a positive serologic test does not necessarily mean that the baby has syphilis, since antibodies are transferred to the fetal circulation from the mother. A negative test likewise is unreliable, for the infant may not have developed antibodies of his own. By the time he is three months of age the positive serologic reaction due to passive transfer from the mother has usually been lost, and he has nearly always established his own antibodies if he is going to do so. At six months serologic tests can be relied on with almost complete certainty. A single positive serologic test, however, is never adequate evidence for treatment at any age unless symptoms or roentgenographic signs are present, since the reaction may be due to an error in the laboratory or to one of the conditions which produce falsely positive reactions. A second test should be obtained promptly and decision concerning treatment delayed until it has been ascertained that no error has been made.

When there is evidence of disease, treatment should be instituted immediately, since irreparable damage may otherwise occur even within a week. If the infant has a positive serologic test and no clinical evidence of disease, the decision concerning treatment may be deferred, pending determination of titrated serologic tests at monthly intervals. If there is no decrease in titer at three months or disappearance of the reaction by six

months, he should be treated. Many physicians now prefer to treat an infant with penicillin immediately after birth if there is any doubt as to whether he is infected with syphilis, and especially if there is any doubt about the opportunity for subsequent observation of the infant.

**Prognosis.** Many syphilitic infants are born dead. If syphilis is recognized early and treated adequately, the infant will usually grow and develop normally. The lesions disappear rapidly, and few, if any, stigmas remain. When treatment is begun after manifestations have developed, the child is usually left with stigmas. Death may, however, occur in spite of treatment; rarely treatment, perhaps by rapidly destroying many spirochetes, seems to hasten the fatal outcome. Secondary sepsis with pyogenic organisms may also cause death. That infected infants may survive without treatment is evidenced by positive serologic reactions in children who are otherwise apparently normal. Interstitial keratitis often results in impaired vision. Meningovascular syphilis leaves the child in a pathetic, useless state.

**Prevention.** If preventive medicine were practiced ideally, congenital syphilis would rarely occur. Tests for syphilis should be obtained on every pregnant woman as early in pregnancy as possible and should be repeated about the sixth or seventh month. Adequate treatment of the mother before or during pregnancy will prevent the development of syphilis in all but 1 or 2 per cent of instances. Even inadequate treatment of the mother will greatly reduce the incidence of the disease in the offspring.

Penicillin passes through the placental barrier and can provide a sufficient bacteriostatic level in the fetal circulation to prevent and treat prenatal syphilis successfully.

#### TREATMENT OF CONGENITAL SYPHILIS

See Diagnosis for selection of patients for treatment.

Penicillin is the treatment of choice for all forms of congenital as well as acquired syphilis. It causes disappearance of the *Treponema pallidum* from early lesions, initiates healing more rapidly than the therapeutic agents formerly used, and greatly shortens the course of therapy. Secondary infections, common in syphilitic infants, may also be favorably influenced. Therapy of early syphilis is usually given over a period of fifteen days with a total dose of not less than 50,000 units of penicillin per pound of body weight.

It should always be given by injection. If crystalline penicillin is used, one one-hundred twentieth of the total dose is given every three hours, and, if procaine G penicillin in an absorption-delaying vehicle is used, 75,000 to 150,000 units are given once daily. Older children with late congenital syphilis are given up to four and one-half million or more units of penicillin over a period of fifteen days. Although about half of the children will suffer a febrile Herxheimer reaction, most pediatricians agree that there should be no reduction in the initial dose. Such treatment has produced complete healing in almost 100 per cent of infants under four months of age. Serologic reversal may be expected by one year and occurs in almost all instances by two years of age. As treatment is instituted at increasingly later ages, the serologic response is less complete and in late congenital syphilis is hardly noticeable.

### NEUROSYPHILIS

Abnormalities of the cerebrospinal fluid in early congenital syphilis disappear as the other lesions heal. Meningovascular syphilis, paresis and tabes apparently respond better to penicillin therapy than they did to formerly used chemotherapy. Cerebrospinal fluid findings revert slowly to normal, but irreparable damage to nerve tissue often prevents restoration to normal function.

### INTERSTITIAL KERATITIS

The response to penicillin is no better than to older forms of therapy. Penicillin should, however, be given to untreated patients for its general systemic effect. Topical cortisone or hydrocortisone acetate, 5 mg. per milliliter in isotonic saline solution applied every hour or two to the affected eye, relieves symptoms promptly in early cases. It also resolves dense infiltration and vascularization of the cornea, but must often be continued for a long time. Drops or ointment should be applied several times a day when improvement is assured. Cortisone cannot be expected to have any effect on established scars or necrotic tissue. Systemic steroid therapy or fever therapy is used only when there is failure with topical therapy. The pupil should be kept dilated until all signs of active disease are gone.

### ACQUIRED SYPHILIS

With the decrease in congenital syphilis, acquired syphilis in children has come to as-

FIG. 146. Chancre of the lip in a child of 1½ years. Spirochetes were easily demonstrated in scrapings from the lesion.

sume a relatively more important role. Ten per cent of the children with syphilis in the Vanderbilt Clinic had acquired syphilis. Smith was able to collect 125 undoubted instances of acquired syphilis in children up to eleven years of age. He found that, in children over ten years of age, syphilis acquired in the usual way by sexual contact was common.

The mouth, face, neck, genitals and anus are the most common sites of primary chancre (Fig. 146). The infection is most often acquired from intimate contact with some infected adult, through sexual play with a playmate or by attempts at sexual intercourse, usually by an adult. Several cases of syphilis acquired by transfusion of blood are reported. The disease, unless acquired in early infancy, resembles that in the adult. "Snuffles" and extensive involvement of the bones are uncommon. Often the chancre remains unnoticed, and a skin rash or condylomas, particularly around the anus, are the first symptoms observed.

More cases of acquired syphilis in childhood undoubtedly exist than are recognized, since, unless there is proof that syphilis is acquired, one is likely to conclude that the disease in a young child is congenital in origin. If the infection is discovered early, the response to treatment with penicillin is usually excellent, with prompt disappearance of lesions and reversal of the serologic reaction.

## LEPTOSPIROSIS

(WEIL'S DISEASE AND CANICOLA FEVER)

Of the many varieties of *Leptospira* which cause infectious disease in man and animals, two have been demonstrated to be important in the United States. *Leptospira icterohæmorrhagiae*, transmitted by the rat, causes spirochetel jaundice, or Weil's disease, and *Leptospira canicola*, carried by the dog, initiates canicola fever. Human infection may result from ingestion of food or water contaminated by the urine of infected rats or dogs, or by direct contact through the abraded skin. In the earliest clinical phase of the infections the organisms are present in the blood, and are thus responsible for inflammatory changes in striated muscle, liver, kidney, eyes and meninges. The incubation periods are from one to two weeks.

Infection by either organism may result in several different clinical pictures. The severe form of either disease is characterized by sudden onset, often with a chill, followed by a remittent fever ranging between 102° and 104° F. Muscular pains, headache, vomiting and suffusion of the conjunctiva follow. Jaundice and hemorrhage into the skin usually appear on the third to fifth day. Confusion, disorientation and coma may ensue. There is reduction of urinary output; the urine contains albumin, casts, bile and, at times, red blood cells. There is retention of nitrog-

enous waste products in the blood, and in fatal cases the kidney involvement is an important factor. Leukocytosis with shift to the left is usually present, and the cerebrospinal fluid frequently shows the changes of serous meningitis. The duration of the disease may be as long as two months, and relapses sometimes occur. On the other hand, the clinical course may be so mild that fever and conjunctival suffusion are the only symptoms.

A pure meningeal form may occur without icterus or renal involvement. The onset is sudden with headache and photophobia and at times is accompanied by suffusion of the eyes. There may be muscular pain severe enough to prevent movement of one or more extremities. Nuchal rigidity is slight, and other meningeal signs are often absent. The cerebrospinal fluid is clear and colorless and under slightly increased pressure, and contains from 50 to 500 cells, which are predominantly polymorphonuclears at the onset, but change to lymphocytes as the disease progresses. The sugar, chloride and protein content is not significantly affected. This form of the disease is of short duration. Leukocytosis is absent.

Spirochetes may be isolated from the blood early in either disease by culture or animal inoculation, from the urine during the second to fourth week and from the cerebrospinal fluid. Specific antibodies which appear in the blood during the second week are often present in high titers and persist for two to three years. There is some cross agglutination between the two leptospira. The case fatality rate varies from 4 to 48 per cent; it is lower in children than in adults; death is rare in nonicteric cases.

There is no specific therapy for either disease. Good therapeutic effects have been claimed for both penicillin and Aureomycin, particularly when administered early, but these claims have not been adequately established.

## INFECTIONS TRANSMITTED BY RAT BITES

### RAT-BITE FEVER (SODOKU)

**Etiology.** Rat bites are common in children, particularly among those living in poorly constructed houses and congested areas. Though such bites may be the cause of any of the more common forms of septicemia or of tetanus, two distinct diseases are directly attributable to the bite of a rat. One, the classic type of rat-bite fever, or sodoku, is caused by the *Spirillum minus*, a spiral organism 2 to 10 microns in length, with spirals at intervals of about 1 micron. Man is infected by the bite of an infected rodent.

The other disease, known as Haverhill fever, or erythema arthriticum epidemicum, is caused by the *Streptobacillus moniliformis*. It is possible that some of the confusion in the differentiation of the two diseases is due not only to the similarity of many of the symptoms, but also to the fact that they may occasionally exist together.

**Clinical Manifestations.** Clinically, rat-bite fever is characterized by primary healing of the bite wound, followed in one to four weeks by painful induration at this site, with development of a chancre-like ulcer and of regional lymphadenopathy. The temperature rises suddenly to 102° to 105° F. (38.8° to 40.5° C.), and a peculiar rash appears, consisting of slightly raised bluish-red macules 1 to 10 cm. in diameter. The rash is usually prominent over the trunk and face and may be so around the area of the bite (Fig. 147). The symptoms are those of a severe, generalized febrile disease with nausea, vomiting, generalized aching and occasionally delirium or convulsions.

After three to four days the temperature subsides, the local lesion and regional nodes become less painful, and the eruption tends to disappear. An afebrile period of three to five days ensues, followed by a repetition of all the signs and symptoms, with the onset of another bout of fever. Intermittent fever with remissions, in which the patient usually appears well, may continue for months. The site of the rat bite does not always become inflamed, and at times the characteristic rash appears only with the second or third rise in temperature. Except in these instances the diagnosis of rat-bite fever is not difficult.

**Diagnosis.** *Spirillum minus* may be seen in darkfield examination of serum obtained from

FIG. 147. The typical rash of the spirochetal form of rat-bite fever and the local lesion.

scrapings of the original lesion. Identification of the organism is usually obtained by intraperitoneal inoculation of animals with serum from the primary lesion or material from an infected lymph node or blood. White mice or guinea pigs free of the disease are the most suitable subjects. The organism can be demonstrated in the blood of the animal, four to eight days after inoculation, by the darkfield microscope or by suitable staining methods.

The leukocyte count is increased to about 10,000 to 20,000 cells per cubic millimeter with each febrile period. The flocculation tests for syphilis as well as the Wassermann test often becomes positive.

**Prognosis and Treatment.** The disease may be fatal during the first paroxysm of fever or may lead to profound anemia and cachexia and, if untreated, to a long, protracted course. Treatment with penicillin will almost always bring about a prompt cure.

### HAVERHILL FEVER\*

(ERYTHEMA ARTHRITICUM EPIDEMICUM)

**Etiology.** *Streptobacillus moniliformis*, the causative agent of Haverhill fever, is a microorganism which exhibits extreme pleomorphism. The disease is transmitted to man by the bite of an infected rat and by contaminated food and liquids.

\* From an etiologic standpoint, Haverhill fever is not a spirochetal disease, but is included here in association with rat-bite fever because its usual vector is the rat.

**Symptoms.** The clinical symptoms of the disease are intermittent fever, rash and arthritis. The incubation period is usually three to five days. Leukocytosis is slight or absent, and the skin eruption finer and often less marked than in rat-bite fever. The febrile paroxysms are less regular in duration and severity and may be inapparent in small infants. The region of the bite may suppurate. The most characteristic feature of the disease is the arthritis. Both large and small joints are involved. The swelling, redness and tenderness of the joints are at first remittent with the fever. Later, if suppuration occurs, large amounts of fluid accumulate in the joint cavity.

**Diagnosis.** *Streptobacillus moniliformis* can be isolated from the patient's blood or from fluid obtained from infected joints. The addition of sterile ascitic fluid to the medium

(30 per cent by volume) is recommended. After two or three days of incubation characteristic "fluff balls" appear. The organism is best shown by preparing air-dried smears stained by either Wayson's method or alkaline methylene blue. The microorganisms appear in preparations as chains of bacilli which have beadlike swellings. Specific agglutinins may be found in the serum after the disease has been present for two weeks or more.

**Prognosis and Treatment.** The disease may last for weeks or months, but is apparently never fatal. Treatment with penicillin produces rapid cure.

# VIRAL INFECTIONS AND THOSE PRESUMED TO BE CAUSED BY VIRUSES

## MEASLES

(RUBEOLA)

**Definition.** Measles is an acute communicable disease commonly occurring in childhood. It is characterized by three stages: (1) an incubation stage of approximately ten to twelve days with few, if any, signs or symptoms; (2) a prodromal stage with enanthem on the buccal (Koplik's spots) and pharyngeal mucosa, rising temperature, slight conjunctivitis, coryza and an increasingly severe cough; and (3) a final stage with morbilliform or maculopapular rash erupting successively over the neck and face, body, arms and legs and accompanied by high fever.

**History.** Sydenham described the disease as a separate entity in the seventeenth century.

In 1759 a Scotsman, Home, transmitted the disease by scarifying the arms of susceptibles and applying bandages soaked in blood from subjects during the early stages of measles. Hektoen in 1905 confirmed this observation by injecting blood from subjects in the early stage of measles into susceptible persons.

Anderson and Goldberger in 1911 first produced measles in *Macaca mulatta* (rhesus monkey) by injection of filtered material from acute cases and suggested a virus as the causative agent. The virus was later grown on the chorio-allantois of the chick embryo by Rake and Shaffer from filtered nasopharyngeal washings and blood of patients in an early phase of measles. With Stokes and O'Neil they demonstrated the presence of the virus by inoculation of monkeys and susceptible children with material from numerous chorio-allantoic passages. Plotz had apparently produced measles previously in one monkey after ten passages of the virus in chick embryo tissue cultures. Enders and his co-workers established the virus in successive tissue culture passages.

**Etiology.** The virus is present in the nasopharyngeal secretions and in the blood, at least during the prodromal period and for a short time after the appearance of the rash. It will pass through a Seitz EK or Berkefeld N filter. It can remain active for at least thirty-four hours at room temperature, for at least fifteen weeks after desiccation from the frozen state, for at least four weeks in storage at  $-72^{\circ}\text{C}$ . to  $-35^{\circ}\text{C}$ ., and for several days at  $0^{\circ}\text{C}$ . It is readily inactivated at a low pH.

The production of typical giant cells in

successive passages in tissue cultures of human renal cells and in human amnion cells by Enders et al. has made possible the development of neutralization and complement fixation tests. Virus cultivated in the chorio-allantois has produced modified measles in the *Macaca mulatta* and in man. After such modified disease the monkeys usually have shown immunity when challenged with active virus. In man, after such modified disease, the resistance to challenge inoculation has been variable.

**Epidemiology.** Epidemics of measles occur irregularly, but in large urban centers they appear at two- to four-year intervals, probably resulting from the accumulation of large new groups of susceptible children. Epidemics commonly appear in the late winter or early spring. The virus spread is not dependent on subclinical cases, since approximately 98 per cent of the population exhibit frank measles. There is no evidence that a carrier state exists, nor has any other mode of interepidemic transmission been established. During an epidemic the air-borne route appears to be the commonest mode of spread, although contact or direct "droplet hits" from speaking, sneezing or coughing are also important means of cross infection. Rarely third persons may carry the virus on clothing if the time interval from source to susceptible is not great. Since the virus is more readily transmitted during the prodromal stage, it is difficult to detect a case in time to prevent spread to susceptibles. The differences in severity are probably associated with secondarily invading bacteria, which are also often responsible for the complications.

In large urban centers epidemics are more frequent than in less thickly populated areas, and a larger percentage of children are infected during the preschool years. Epidemics in army posts have been attributed to the collection of adult susceptibles from rural communities. Approximately 90 per cent of susceptible children under six years of age with family exposure during an epidemic will contract the disease. Most of the remaining 10 per cent will contract measles subsequently.

Rarely a person does not acquire immunity from an attack and has measles repeatedly,

perhaps as the result of hypogammaglobulinemia or agammaglobulinemia. In most instances so-called second or third attacks in children are actually German measles or exanthem subitum, which has been improperly diagnosed. Although immunity starts soon after subsidence of the fever and rash, rarely a patient will suffer two attacks of measles in rapid succession.

Infants acquire immunity transplacentally from mothers who have had measles. This immunity is usually complete for the first four to six months of life and disappears rapidly in the next month or two. Infants of susceptible mothers have no such immunity and may contract the disease with the mother at any time before or after delivery.

Most evidence suggests that solid immunity is produced in children whose measles is attenuated by human immune serum.

**Pathology.** The essential lesion of measles is found in the skin, in the mucous membranes of the nasopharynx and bronchi, and in the conjunctivas. It is a reaction of the capillary bed to the invading virus. Serous exudate and proliferation of mononuclear cells and a few polymorphonuclear cells occur around the capillaries. There is usually hyperplasia of the lymphoid tissue, where multinucleated giant cells, often 100 microns in diameter with as many as 100 nuclei, may be found. In the skin the reaction is particularly marked about the sebaceous glands and hair follicles. Koplik's spots\* consist of serous exudate and proliferation of endothelial cells similar to those noted in the skin rash. Rarely, ulceration occurs in the center of the lesions. There is a general inflammatory reaction of the buccal and pharyngeal mucosa which extends into the lymphoid tissue and the tracheobronchial mucous membrane. Bronchopneumonia frequently occurs in severe measles as the result of bacterial invasion.

**Clinical Manifestations.** The incubation period is approximately ten to twelve days if the first symptoms are selected as the time of onset, or approximately fourteen days if the appearance of the rash is selected; rarely it may be as short as six to ten days. A slight rise of temperature may occur nine or ten days from the date of infection and then subside for twenty-four to forty-eight hours.

The prodromal phase is characterized by fever, a slight hacking cough, coryza and

\* So-called Koplik's spots were apparently first described by Dr. John Quier in his Fifth Letter written from the West Indies to London in 1774.

conjunctivitis, which practically always precede the Koplik's spots, the pathognomonic sign of measles—one of the few in the field of medicine. As a rule the maculopapular or morbilliform rash of measles then appears within a day or two. Rarely the interval may be four or five days, or occasionally the rash precedes the spots or appears at the same time. This prodromal phase of the disease lasts approximately four to five days. There may be a considerable variation in the time of appearance of one sign or symptom in relation to others. An enanthem or red mottling may occur with or without Koplik's spots over the hard and soft palates. Koplik's spots are grayish-white dots, usually as small as grains of sand, with a slight reddish areola; occasionally they are hemorrhagic. They tend to occur opposite the lower molars, but may spread irregularly over the rest of the buccal mucosa. Rarely they are found within the midportion of the lower lip, on the palate and on the lacrimal caruncle. They appear and disappear rapidly, usually within twelve to eighteen hours. As they fade there may remain red, spotty discolorations of the mucosa. Examination for Koplik's spots should be carried out, if possible, in bright daylight. Trauma from biting the cheeks may result in tiny ulcers with an areola which may simulate them.

The prodromal phase lasts approximately four to five days. Occasionally it may be unusually severe, being ushered in by sudden high fever, at times with convulsions and even bronchopneumonia. Such a prodromal phase accounts for the mistaken idea that hot baths are effective in "bringing out" the rash, since laymen recognize that, when the rash is full-blown, improvement generally follows. Usually the coryza, fever and cough are increasingly severe up to the time the rash has covered the body. The conjunctival inflammation, with redness, swelling and photophobia, leads one to suspect measles before the Koplik's spots appear. In addition a transverse line of conjunctival inflammation, as described by Stimson, sharply demarcated along the eyelid margin, may be of diagnostic assistance in the prodroma stage. As the entire conjunctiva is involved the line disappears.

The temperature tends to rise abruptly as the rash appears and usually reaches 104° or 105° F. When the rash reaches the leg and feet, within about two days, the symptoms subside rapidly in uncomplicated cases. The patient up to this point may appear

FIG. 148. Morbilliform rash of measles.

desperately ill, and yet within twenty-four hours after the drop in temperature, which is usually abrupt, he will appear to be essentially well.

The rash usually starts as faint macules on the upper lateral parts of the neck, along the hairline and on the posterior parts of the cheeks. The individual lesions become increasingly maculopapular or morbilliform in appearance as the rash spreads rapidly over the entire face, neck, upper arms and upper part of the chest within approximately the first twenty-four hours (Figs. 148, 149). During the succeeding twenty-four hours it spreads over the back, abdomen, entire arms and thighs. As it finally reaches the feet on the second or third day it is beginning to fade on the face. The fading of the rash proceeds downward in the same sequence as that of its appearance. The severity of the disease is directly related to the extent and confluence of the rash. In mild measles the rash tends not to be confluent, and in very mild cases there are few, if any, lesions on the legs. In severe measles the rash is confluent, the skin being completely covered, including the palms of the hands and soles of the feet, and the face is swollen and disfigured.

The rash is often slightly hemorrhagic; in severe cases with a confluent rash, petechiae may be present in large numbers, and there may be extensive ecchymoses. Itching is generally slight, although on occasion it may be annoying. As the rash fades, the coppery appearance changes to a brownish discoloration, which disappears within approximately seven to ten days. There is a fine, branny type of desquamation, which may be extensive in severe measles.

Variations in types of rash may occur. In-

frequently a slight urticarial, a faint macular or a scarlatiniform rash may appear during the early prodromal stage and disappear well in advance of the typical rash. Complete absence of rash is rare except in patients who have received human antibodies during the incubation period. When cardiac failure supervenes in severe cases, the rash usually recedes; occasionally death may occur before the rash has appeared. In the hemorrhagic type of measles ("black measles") bleeding may occur from the mouth, nose or bowel. In mild cases the rash may be less macular and more nearly pinpoint, closely resembling that of scarlet fever.

Lymph nodes at the angle of the jaw and in the posterior cervical region are usually enlarged, and mild splenomegaly occurs at times. In infants and small children gastrointestinal symptoms, such as diarrhea and vomiting, and otitis media and bronchopneumonia are more common than in older children.

The white blood cell count is lower than usual with a relative lymphocytosis.

**Differential Diagnosis.** The most important diseases from which measles must be differentiated are German measles, scarlet fever and exanthem subitum.

In *German measles* there are no Koplik's spots and rarely cough, conjunctivitis or photophobia. The enlarged suboccipital, posterior cervical and postauricular lymph nodes in German measles also help to distinguish it. The rashes are somewhat similar

FIG. 149. Purpuric rash of measles.

only when measles is not severe; on the second day the rash of German measles is frequently fading or pinpoint in appearance, closely resembling that of scarlet fever. Fever is minimal in contrast to the typically high temperatures during the height of the rash in measles.

*Scarlet fever* (see p. 404): Mild cases of either disease may lack a number of their distinguishing features.

The rash of *exanthem subitum* appears as the fever subsides, and the disease is thus readily distinguished from measles.

Rashes from drugs or serum sickness are usually not difficult to differentiate from that of severe measles, but those caused by phenobarbital, Dilantin and the sulfonamides may closely resemble that of mild measles. Koplik's spots, cough and conjunctivitis in measles are differentiating factors.

**Complications.** The chief complications of measles are otitis media, bronchopneumonia, and encephalitis. Noma of the cheeks and gangrene elsewhere are rare complications in severe cases.

*Bronchopneumonia* may be caused by the measles virus, but is more commonly due to secondarily invading bacteria, particularly the *Pneumococcus*, *Streptococcus*, *Staphylococcus* and *Hemophilus influenzae*. Laryngitis with hoarseness, tracheitis and bronchitis, commonly present, may be due to the virus alone. The greatest danger from bronchopneumonia is in the youngest age groups and in very old persons. It usually occurs late in the course of measles. One of the potential dangers of measles is the exacerbation of a tuberculous focus.

Whether *encephalitis* as a complication is due to a variety of agents or to a single one is not established, but available evidence suggests that the measles virus itself may be responsible. The symptoms and course do not differ from those of other postinfectious encephalitides (p. 546).

**Prognosis.** Case fatality rates in the United States have decreased in recent years to low levels for all age groups, in part perhaps because of improved living conditions, but also because of effective antibacterial therapy for the treatment of secondary infections.

When measles is planted upon a highly susceptible population, the results may be disastrous. Such an occurrence in the Faroe Islands in 1846 resulted in the deaths of about one-quarter, nearly 2000, of the total population regardless of age. On the other hand, in a recent epidemic in Greenland with

100 per cent involvement of 4257 inhabitants the mortality rate was only 1.8 per cent, although 45 per cent of them had complications. At Ungava Bay, Canada, where 99 per cent of 900 persons had measles, the mortality rate was 7 per cent.

**Prophylaxis.** Quarantine is of little value, owing to the high communicability of the disease during its prodromal stage, when its presence is usually not suspected. Susceptibles known to have been exposed to the first case or group of cases may be permitted freedom for one week and then kept under strict isolation for eight days. Under ordinary school or home conditions such attempts at isolation are ineffectual. The isolation of children with measles will decrease the opportunities for them to acquire secondary bacterial infections. Quarantine of the patient may be lifted one to two days after return of the temperature to normal.

The value of *active immunization* procedures must await further studies with the measles virus grown in chick embryo tissue cultures.

*Passive immunization* with pooled adult serum, pooled convalescent serum, placental globulin and gamma globulin of pooled plasma is effective for prevention and attenuation of measles.

For attenuation intramuscular injections are best made in the first seven days after exposure; the amount of gamma globulin required is considered to be 0.02 to 0.025 cc. per pound (0.045 to 0.05 cc. per kilogram) of body weight. Gamma globulin, including that now prepared in the United States from placental blood, is approximately twenty-five times as potent in antibody titer as pooled adult serum.

For prevention the amount required of these agents is approximately three to four times as large as for attenuation, and they must be administered within seven days after exposure. There is great advantage in the use of gamma globulin because of the small volume required, the almost complete absence of local or general reactions, and the absence of the virus of hepatitis.

The modified clinical patterns resulting from such attenuation vary from instances in which there are few or no symptoms with only mild fever to, rarely, little or no modification. The rash and Koplik's spots, as well as the coryza and cough, may be slight or absent.

After the seventh or eighth day of incubation the amounts of immune bodies must be

increased greatly for any degree of protection. If the injection is delayed until the ninth, tenth or eleventh day, slight fever may already have started, and only slight modification of the disease may be expected.

**Treatment.** It is possible that ten to twenty times the usual amounts of gamma globulin will modify the disease to some extent even when injected in the prodromal stage, or at least the danger of complications may be lessened. Greenberg et al. found that among 165 cases of measles encephalitis only one patient had had gamma globulin prophylactically. There is suggestive evidence that large doses of gamma globulin, 0.40 to 1.0 ml. per pound of body weight, may prevent death and lessen residual complications in measles encephalitis; there are also some favorable reports from the use of corticoids and corticotropin. The real value of each method of treatment awaits confirmation.

The ordinary treatment for children with high fever and an irritating cough suffices for measles, except that care must be taken to protect the eyes from strong light; ordinary daylight is not irritating. Sedatives, antipyretics for high fever, proper skin lotions for itching or irritation, complete bed rest and an adequate fluid intake are the usual requirements. Humidification of the room may be necessary for laryngitis or an excessively irritating cough, and it is best to keep the room comfortably warm rather than cool. The complications of otitis media and pneumonia require appropriate antibacterial therapy.
